Electron – heavy nucleus bremsstrahlung at highly relativistic impact energies

D. H. Jakubassa-Amundsen
Mathematics Institute, University of Munich, Theresienstrasse 39, 80333 Munich, Germany

Abstract

Bremsstrahlung including the polarization correlations is revisited by presenting a new model which is applied to the short-wavelength limit. The fast incoming electron is described by a Sommerfeld-Maue function whereas for the outgoing electron an exact Dirac function is used. The cross section for electrons radiatively scattered from gold is calculated in the impact energy range 0.2–10 MeV and is compared to results from the Elwert-Haug theory and to available experimental data and relativistic partial-wave calculations. As an ultrarelativistic benchmark, the polarization correlations for 10 MeV electrons and 3–10 MeV photons are also given.

1 Introduction

With the recent experimental and theoretical investigation of radiative electron capture and radiative ionization by bare, heavy projectiles aiming at differential cross sections [1]–[3] and linear photon polarization [4]–[6], the interest in the bremsstrahlung process has been revived. The linear polarization \( P_1 \) of bremsstrahlung photons emitted from unpolarized high-energy electrons colliding with target atoms was extensively studied some fifty years ago (see e.g. [7]–[13]). Also the spin asymmetry \( A \) from polarized electrons was measured and interpreted [14]–[19]. However, the predictions for the further polarization correlations which relate to linearly polarized photons, published by Tseng and Pratt [10] for the wide impact energy range from 5 keV to 1 MeV, have never been tested experimentally.

With the advent of novel-type Compton polarimeters a new series of experiments has been started to measure for 100 keV electrons the dependence of all these polarization correlations on photon energy and angle [20, 21]. It is planned to extend the measurements to several MeV impact energy in the near future [22], which calls for theoretical predictions in this highly relativistic regime.

Two theoretical prescriptions have become standard for bremsstrahlung, both treating the photon field to first order. The first model, with results for the differential cross section and for \( P_1 \) dates back to Bethe, Olsen and Maximon [23, 7] in the ultrarelativistic regime, as well as to Elwert and Haug [24, 9] for weakly relativistic collision systems. In this theory the electronic wavefunctions in the potential of a bare target nucleus of charge number \( Z \) are described by the Sommerfeld-Maue (SM) functions [25]. These functions reproduce the Coulomb wavefunctions in the nonrelativistic regime and approximate the exact Dirac functions for the higher energies. More precisely, they agree with the Dirac functions up to order \( Z \alpha \) (where \( \alpha = e^2/\hbar c \) is the fine structure constant), i.e. in the weak-relativistic regime. However, they become again exact in the ultrarelativistic regime, provided the distance \( r \) from the nucleus.
is much larger than $Z\alpha/p$ where $p$ is the electron momentum [26]. In consistency with these two regions of applicability, a higher-order contribution to the transition matrix element is dropped such that the remaining radiation matrix element can be expressed in closed form. This is the advantage of the SM theory (which has become known by the name Elwert-Haug theory). Based on this theory, Olsen and Maximon [7] have extracted a simple analytic formula for $P_1$ in the ultrarelativistic regime.

The second model differs from the first by using exact Dirac functions in place of the SM functions, with no further approximation. This necessitates a partial-wave representation of the differential cross section [8, 27, 28]. While SM results are available up to 15 MeV [9, 24] and beyond 20 MeV impact energy [7], partial-wave results exist mostly at energies up to 2 MeV [10, 29]. The reason is the strongly increasing numerical effort involved since at higher energies the number of partial waves, needed for convergence, becomes very large. There are also a few results at 5 MeV and beyond [30, 31], and even at the ultrarelativistic limit [32]. However, in these high-energy partial-wave calculations the photon angle is not resolved.

Fig.1 gives an overview of existing results for the extrema of $P_1$ as a function of photon emission angle. The case is studied where the photon carries away 90 percent of the energy of the electron, which impinges on gold, while the scattered electron is not observed. Included are SM results covering the whole impact energy region under consideration. Both models agree fairly well with the available experimental data, showing that the two extrema merge and that $P_1$ remains finite (of order unity [7]) in the ultrarelativistic regime.

The fact that the polarization correlations related to linearly polarized photons are, with the exception of $P_1$, purely relativistic (since they vanish in the nonrelativistic limit and increase with $Z\alpha$ [10]) makes them a sensitive tool for studying the validity of the SM functions beyond the weak-relativistic regime. The judgement of the SM functions by a direct comparison between the SM theory and the partial-wave model is, however, hampered by two facts. First, there are two SM functions, often relating to very different energies, which enter into the transition matrix element and second, the SM theory is subject to an additional approximation beyond replacing the Dirac functions by the SM functions.

Therefore we introduce a new prescription, termed Dirac–Sommerfeld-Maue (DSM) theory, where only one SM function, representing the fast (initial) electron, is introduced into the radiation matrix element. The outgoing electron, on the other hand, is described by an exact Dirac function. Such a hybrid theory where the initial and final wavefunctions are not eigenstates to the same Hamiltonian may suffer from nonorthogonality effects or from inconsistencies. In fact, orthogonality between the initial and final states holds only to first order in $Z\alpha$ (like in the SM theory) except in the ultrarelativistic limit. Our argumentation in favour of the DSM approach is the following. There is a one-to-one correspondence between the SM functions and the nonrelativistic Coulomb waves since the respective transformation operator, $e^{ikr}(1 - \frac{Z\alpha}{\hbar c} (\alpha \nabla)) e^{-ikr}$ (see equation (2.3) below) is invertible. Therefore, together with the bound states, the SM functions form a complete set and hence a basis for the expansion of a Dirac wave. Replacing the Dirac wave by an SM function of the same momentum is therefore equivalent to truncating this expansion after the first term. Hence the DSM model is at high enough energy (i.e. when the difference between the two functions is small and the remaining terms of the expansion of minor importance) a consistent perturbative approach. Its great advantage as compared to the exact relativistic theory is the omission of a partial-wave expansion of the initial state which at 10 MeV (and $Z > 40$) would require more than 120 partial waves for an accuracy of the differential cross section below 5 percent [31].

Only bare nuclei are considered in the present calculations. We will concentrate mostly on the short-wavelength limit (SWL), the tip of the bremsstrahlung spectrum where the whole collision energy is transferred to the photon, leaving the outgoing electron at the continuum threshold of the nucleus. Such an SWL collision system has several advantages. First, for high-$Z$ targets, the slow outgoing electron can, according to the criteria given above, never be well described by an SM function, calling for an improvement beyond the SM model. Second, due to the large momentum transferred to the nucleus, regions of space close to the nucleus are selected which are the crucial ones for testing the validity of the SM function at high energy. Third, for sufficiently high impact energies, only a few partial waves of the
There exist some SM and partial-wave results at the SWL when Z is high. The SM calculations are done for the differential cross sections [24, 31] and $P_1$ [9] up to 15 MeV. The partial-wave results also concern the differential cross sections [8, 33, 34, 31] and $P_1$ [8, 34] at energies mostly below 2 MeV. In [35, 36, 34] another noticeable advantage of the SWL was explored, the smooth transition between bremsstrahlung at threshold and radiative recombination (RR) of a free electron into infinitely high-lying Rydberg states of the target. By extrapolating RR to the continuum threshold, partial-wave results up to 5 MeV can readily be obtained [37]. Such results, extended to the polarization correlations pertaining to doubly differential cross sections, were used in [38] to show that for heavy nuclei the electron energy has to exceed 5 MeV in order to describe all polarization correlations accurately with the help of SM functions.

In Section 2 we formulate the DSM theory for the SWL and furnish the numerical details in Section 3. Results for the doubly differential photon emission cross section (integrated over the electronic angular distribution) for 0.18 – 10 MeV electrons scattering from Au$^{79+}$ are given in Section 4 and are compared with the SM theory, the partial-wave model and experiment. The relation between the differential cross sections for radiative recombination and bremsstrahlung at threshold is explored to extract additional partial-wave results. Finally, for 10 MeV electrons, results are presented for all polarization correlations relating to linearly polarized photons. There, the DSM theory is used at the SWL and the SM theory for the lower photon energies (Section 5). Concluding remarks are given in Section 6. Atomic units ($h = m = e = 1$) are used unless indicated otherwise.

2 The DSM theory for bremsstrahlung

We consider the scattering of a high-energy electron of (total) energy $E_i$ and spin $\sigma_i$ from a bare point nucleus of charge $Z$ and allow for the simultaneous emission of a bremsstrahlung photon of energy $\omega$. The doubly differential cross section for the emission of the photon into the solid angle $d\Omega_k$ is given by [39, 28, 40]

$$\frac{d^2\sigma}{d\omega d\Omega_k} = \frac{4\pi^2 \omega k_f E_f}{c^3 v} \sum_{\sigma_f} \int d\Omega_f \left| (e_\lambda W_{\text{rad}}(\sigma_f, \sigma_i)) \right|^2$$  \hspace{1cm} (2.1)

where $v$ is the collision velocity. The energy $E_f = \sqrt{(k_f c)^2 + c^2}$ of the scattered electron is fixed by energy conservation, $E_f = E_i - \omega$. Assuming that the electron is not observed we have summed over its final spin $\sigma_f$ and integrated over the solid angle $d\Omega_f$ of emission.

To first order in the electron–photon interaction the transition matrix element reads

$$e_\lambda W_{\text{rad}}(\sigma_f, \sigma_i) = \int dr \psi^{(\sigma_f)+}_{\sigma_f}(r) (\alpha e_\lambda) \psi^{(\sigma_i)}_{\sigma_i}(r) e^{-ikr}.$$ \hspace{1cm} (2.2)

Here, $\alpha = (\alpha_x, \alpha_y, \alpha_z)$ is the vector of Dirac matrices, $e_\lambda$ the polarization direction of the photon and $\psi^{(\sigma_i)}_{\sigma_i}$ and $\psi^{(\sigma_f)}_{\sigma_f}$, respectively, the initial and final states of the electron.

The incoming electron is described by a Sommerfeld-Maue function [7, 26]. Choosing the $z$-axis along the momentum $k_i$ of the incoming electron and employing spherical coordinates, $r = \{r, \vartheta, \varphi\}$, this function reads

$$\psi^{(\sigma_i)}_{\sigma_i}(r) = N_{k_i} e^{ik_i r \cos \vartheta} \left\{ F_1(i\eta_i, 1, ik_i r (1 - \cos \vartheta)) + \frac{iZ}{2r} [\alpha_z (\cos \vartheta - 1) + \frac{1}{2} \alpha_+ \sin \vartheta e^{i\varphi} + \frac{1}{2} \alpha_- \sin \vartheta e^{-i\varphi}] F_1(1 + i\eta_i, 2, ik_i r (1 - \cos \vartheta)) \right\} u^{(\sigma_i)}_{k_i}$$ \hspace{1cm} (2.3)

where $\eta_i = ZE_i/k_i c^2$, $\alpha_\pm = \alpha_x \pm i\alpha_y$, $N_{k_i}$ the normalization constant with the modulus $|N_{k_i}|^2 = \eta_i/(4\pi^2 (1 - e^{-2\eta_i}))$ and $F_1$ a confluent hypergeometric function.
We choose a geometry (see Fig.2) where the collision plane, which is spanned by \( \mathbf{k} \), and the photon momentum \( \mathbf{k} = (\sin \theta_k, 0, \cos \theta_k) \), coincides with the \((x, z)\)-plane. The plane perpendicular to \( \mathbf{k} \) is spanned by the polarization vectors \( \mathbf{e}_{\lambda_1} = (0, 1, 0) \) and \( \mathbf{e}_{\lambda_2} = (-\cos \theta_k, 0, \sin \theta_k) \), and an arbitrary electron spin direction is characterized by \( \mathbf{n}_s = \{1, \alpha_s, \varphi_s\} \). Then a fixed photon polarization \( \mathbf{e}_\lambda \) and electron plane-wave spinor \( u_{k_i}^{(\sigma)} \) are represented in the following way [41]

\[
e_{\lambda} = \sin \varphi_{\lambda} \mathbf{e}_{\lambda_1} + \cos \varphi_{\lambda} \mathbf{e}_{\lambda_2}, \quad \varphi_{\lambda} \in [0, \pi),
\]

\[
u_{k_i}^{(\sigma)} = e^{-i\varphi_{\lambda}/2} \cos \frac{\alpha_s}{2} u_{k_i}^{(+)} + e^{+i\varphi_{\lambda}/2} \sin \frac{\alpha_s}{2} u_{k_i}^{(-)}, \quad \alpha_s, \varphi_s \in [0, 2\pi),
\]

where \( u_{k_i}^{(+)} = C_{k_i}(1, 0, ck_i/(E_i+\epsilon^2), 0) \), \( u_{k_i}^{(-)} = C_{k_i}(0, 1, 0, -ck_i/(E_i+\epsilon^2)) \) with \( C_{k_i} = ((E_i+\epsilon^2)/2E_i)^{1/2} \), are plane-wave 4-spinors with electron spin parallel, respectively antiparallel, to \( \mathbf{k}_i \). For \( \varphi_s = 0 \), \( \alpha_s \) describes spin rotation in the scattering plane.

For the outgoing electron a Dirac continuum state is used, the partial-wave decomposition of which is given by [41]

\[
\psi_{jlm}^{(\sigma)}(\mathbf{r}) = \sum_{jm} \left(w_{\sigma_j}^+ Y_{jlm}(\Omega_f)\right) \psi_{jlm}^+(\mathbf{r}) (-i)^l e^{i\delta_{ij}}
\]

\[
\psi_{jlm}(\mathbf{r}) = \begin{pmatrix} g_{jl}(r) Y_{jlm}(\Omega) \\ if_{jl}(r) Y_{jlm}(\Omega) \end{pmatrix}
\]

where \( Y_{jlm} \) is a vector spherical harmonic [42], \( l' = l \pm 1 \) for \( j = l \pm \frac{1}{2} \), \( w_{\sigma_j} \) is a linear combination of the 2-spinors \( \chi_{\frac{1}{2}} = (1, 0) \) and \( \chi_{-\frac{1}{2}} = (0, 1) \), and \( \delta_{ij} \) is the phase shift.

Let us now restrict ourselves to outgoing electrons at the continuum threshold. When \( k_f \rightarrow 0 \), the radial functions have a simple representation in terms of Bessel functions \( J_\nu \) [43, 8],

\[
f_{jl}(r) = \frac{1}{r} \frac{\kappa}{|\kappa|} \frac{1}{c} \sqrt{\frac{Z}{k_f}} J_{2\gamma}(\sqrt{8Zr})
\]

\[
g_{jl}(r) = -\frac{1}{r} \frac{\kappa}{|\kappa|} \frac{1}{\sqrt{k_f Z}} \left[ \sqrt{2Zr} J_{2\gamma-1}(\sqrt{8Zr}) - (\gamma + \kappa) J_{2\gamma}(\sqrt{8Zr}) \right]
\]

\[
\gamma = \sqrt{\kappa^2 - (Z/c)^2}, \quad \kappa = \begin{cases} -(l+1), & j = l + \frac{1}{2} \\ l, & j = l - \frac{1}{2}. \end{cases}
\]

In the following we make use of the representation of the vector spherical harmonics [42],

\[
Y_{jlm}(\Omega_f) = \sum_{\mu,m_s} Y_{\mu \nu}(\Omega_f) \chi_{m_s} (l \mu \frac{1}{2} m_s | j m), \quad |\mu| \leq l, \quad m_s = \pm \frac{1}{2},
\]

where we have introduced the Clebsch-Gordan coefficients \((\mu \frac{1}{2} m_s | j m)\). Further we apply the orthogonality property of the spherical harmonics \( Y_{jlm} \) and the Clebsch-Gordan coefficients, as well as the completeness relation \( \sum_{\sigma_f} w_{\sigma_f} w_{\sigma_f}^* = 1 \). Then, inserting (2.5) into the radiation matrix element (2.2) and performing the integration over \( \Omega_f \) and the summation over \( \sigma_f \) in (2.1), the doubly differential cross section reduces to an incoherent sum over the final-state partial wave contributions,

\[
\frac{d^2\sigma}{d\omega d\Omega_k} = \frac{4\pi^2 \omega k_f E_f}{c^3 v} \sum_{jlm} |M_{jlm}|^2,
\]

\[
M_{jlm} = \int \frac{d^3r}{\mathbf{r}} \psi_{jlm}^+(\mathbf{r}) (\alpha \mathbf{e}_\lambda) \psi_{\sigma_j}^{(\sigma)}(\mathbf{r}) e^{-ikr(\cos \theta_k \cos \varphi_k + \sin \varphi_k \sin \theta_k \cos \phi_k)}.
\]
3 Numerical details

Since \( \psi^{(\sigma_f)} \) is a threshold continuum state its angular dependence is rather weak. Therefore we have restricted ourselves to include only the \( j = \frac{1}{2} \) and \( j = \frac{3}{2} \) states in the partial-wave expansion. For \( Z = 79 \) and impact energies of 2 MeV and above even the \( d \)-wave contribution \( (j = \frac{3}{2}, l = 2) \) is reduced by several orders of magnitude (except in a narrow forward cone) so that one might even restrict oneself to the \( s \) and \( p \) waves at the higher collision energies (see also [33]).

Let us split \( M_{jlm} \) into the two contributions from the upper and lower component of \( \psi_{jlm} \),

\[
M_{jlm} = \sum_{m_s=\pm \frac{1}{2}} \left( \frac{\chi_{m_s}}{0} \right) (l m-m_s \frac{1}{2} m_s | j m) \int dr \, g_{jlm}(r) \, Y^*_{l,m-m_s}(\Omega) \, \phi_{\lambda_i}(r)
\]

\[
- i \sum_{m_s=\pm \frac{1}{2}} \left( \frac{0}{\chi_{m_s}} \right) (l' m-m_s \frac{1}{2} m_s | j m) \int dr \, f_{jlm}(r) \, Y^*_{l',m-m_s}(\Omega) \, \phi_{\lambda_i}(r)
\]

(3.1)

where \( \phi_{\lambda_i} \) abbreviates the (4-spinor) part of the integrand in \( M_{jlm} \) which multiplies \( \psi_{jlm}^*(r) \).

With the representation of \( Y_{l\mu} \) in terms of the Legendre functions \( P^\mu_l([42],[44, §8.7]) \),

\[
Y_{l\mu}(\Omega) = \sqrt{\frac{2l+1}{4\pi}} \sqrt{\frac{(l-\mu)!}{(l+\mu)!}} P^\mu_l(\cos \vartheta) \, e^{i\mu \varphi},
\]

(3.2)

the \( \varphi \)-integral of the spatial integrals in (3.1) can be done analytically,

\[
\int_0^{2\pi} d\varphi \, e^{-i\mu \varphi} \, e^{-iq_r \sin \vartheta \cos \varphi} \, e^{iks \varphi} = 2\pi (-i)^{|\mu-s|} \, J_{|\mu-s|}(q_r r \sin \vartheta).
\]

(3.3)

Here we have introduced the transverse momentum transfer \( q_r = k \sin \theta_k \), and \( s \in \{0, 1, -1\} \) from the contribution of \( \psi^{(\sigma_f)}(r) \). Thus the double integrals to be performed numerically are, for example,

\[
\int_0^{\infty} dr \, r^{3/2} \, J_{2\gamma-1}(\sqrt{8Zr}) \int_{-1}^{1} d(\cos \vartheta) \, P^\mu_l(\cos \vartheta) \, J_{|\mu-s|}(q_r r \sin \vartheta)
\]

\[
\cdot \, e^{i\eta_r \cos \vartheta} \, F_1(i\eta, 1, ik_r(1-\cos \vartheta)),
\]

(3.4)

where we have introduced the longitudinal momentum transfer, \( q_z = k_i - k \cos \theta_k \). The other integrals which occur are related to (3.4) by replacing \( J_{2\gamma-1}(\sqrt{8Zr}) \) by \( r^{-1/2} J_{2\gamma}(\sqrt{8Zr}) \) or by replacing the confluent hypergeometric function by \( h(\vartheta) \, F_1(1+i\eta, 2, ik_r(1-\cos \vartheta)) \) with \( h(\vartheta) \in \{1, \cos \vartheta, \sin \vartheta\} \), and which are of better convergence than (3.4).

For the treatment of radial integrals involving Bessel functions (which are weakly decaying, but strongly oscillating) we make use of the fact that integrals of the type \( \int_1^\infty dr \, r^{\mu} \, J_{\nu}(ar) \) are convergent for any \( \nu \in \mathbb{R}, \mu \in \mathbb{C} \) [45, Example 144]. This can be shown either by using complex analysis (see e.g. [46] for a related integral) or, for the case \( \mu + \nu > -1 \), by introducing convergence generating functions and considering the limit as they tend to unity [44, p.711, 684],

\[
\lim_{\varepsilon \to 0} \int_0^\infty dr \, r^{\mu} \, J_{\nu}(ar) \, e^{-\varepsilon r} = \frac{2^\mu}{a^{\mu+1}} \frac{\Gamma\left(\frac{\nu+\mu+1}{2}\right)}{\Gamma\left(\frac{\nu+\mu+1}{2}\right)}, \quad a > 0.
\]

(3.5)

Using the fact that the angular integral in (3.4) is a smooth function of \( r \) we can apply the above technique by considering, in place of (3.4), a sequence of integrals,

\[
I_\varepsilon = \int_0^{\tau_{max}(r)} dr \, F(r) \, e^{-\varepsilon r},
\]

(3.6)
where $F$ denotes the $r$-integrand in (3.4) after having performed the angular integral, and $r_{\text{max}}(\epsilon) \sim 8/\epsilon$ is an upper cutoff large enough to assure convergence of the integral for fixed $\epsilon$. The appropriate choice of $\epsilon$ is dictated by the momentum transfer to the nucleus, $q = (q_1^2 + q_2^2)^{1/2} = |k_i - k|$, and the nuclear charge $Z$. It increases (linearly) with $Z$ and also with $q$ (respectively, with photon angle and impact energy). This behaviour is based on the fact that rapid oscillations of the angular-dependent functions (when $q$ is large) lead to a reduction of the radiation matrix element and to convergence at comparatively small $r$. This convergence is also speeded up when the Bessel function $J_1(\sqrt{2Zr})$ changes sign more rapidly (i.e. when $Z$ is large). From this numerics we estimate the accuracy of the differential cross section and $P_1$ to be about 1 percent while the other polarization correlations are less accurate, particularly at the backward photon angles for high impact energies (5–10 percent). Further inaccuracies, predominantly at very small angles, are introduced by terminating the final-state partial-wave series at $j = \frac{3}{2}$. For angles $\theta_k \lesssim 10^\circ$ they amount to 10-15 percent when $E_{i,kin} \sim 200 – 400$ keV, dropping to $\lesssim 5$ percent at 2 MeV.

4 Cross section results

We start by providing the relation between radiative recombination and bremsstrahlung at threshold. As shown in [34] this relation invokes the density of states, $dn/dE$, where $n$ is the main quantum number of the Rydberg state and $E$ the energy. The derivation given below pertains to the experimental treatment of cusp phenomena, but involves strictly the limit $n \to \infty$. For simplicity we consider the nonrelativistic one-electron case. The nonrelativistic theory for bremsstrahlung emission at the SWL ($\omega = \frac{1}{2} v^2$) gives the following formula for the doubly differential cross section [26, 92], assuming only dipole radiation,

$$\frac{d^2\sigma^{\text{SWL}}}{d\omega\,d\Omega_k} = 16Z^3 \frac{1}{c^4v^5} \sin^2 \theta_k.$$  \hfill (4.1)

On the other hand, the differential cross section for the radiative capture of a fast electron into a high Rydberg state of a bare nucleus can be written in the following way [47]

$$\frac{d\sigma(n)}{d\Omega_k} = \frac{(2\pi)^2v}{c^3} \omega_n \varrho_n(v) \sin^2 \theta_k.$$  \hfill (4.2)

In this expression $\omega_n = \frac{1}{2} v^2 + \frac{Z^2}{2n^2}$ is the sum of the collision energy and the binding energy of the Rydberg state. $\varrho_n$ is the electron momentum density, summed over the subshells corresponding to the state $n$,

$$\varrho_n(v) = \sum_{l=0}^{n-1} \sum_{m=-l}^{l} |\tilde{\psi}_{nlm}(v)|^2 = \frac{8Z^5}{\pi^2n^5} \frac{1}{(v^2 + Z^2/n^2)^4},$$  \hfill (4.3)

which decreases with $n$ according to $n^{-3}$ for high $n$. However, in an experimental situation one averages over the resolution $\Delta \omega$ of the photon detector. In particular, at the SWL, all Rydberg states with $n \geq n_0$, where $n_0$ is given by $\Delta \omega = \omega_{n_0} - \frac{1}{2} v^2 = \frac{Z^2}{2n_0^2}$ cannot be resolved (see e.g. [48] for the radiation from quasifree electrons). Therefore the measured quantity is

$$\left\langle \frac{d\sigma^{\text{RR}}}{d\Omega_k} \right\rangle_{\Delta \omega} = \frac{1}{\Delta \omega} \sum_{n=n_0}^{\infty} \frac{d\sigma(n)}{d\Omega_k}.$$  \hfill (4.4)

Now we claim that in the limit $\Delta \omega \to 0$, corresponding to $n_0 \to \infty$, the bremsstrahlung formula (4.1) is retrieved. By using the integral test for convergence [49] we find

$$\lim_{n_0 \to \infty} n_0^2 \sum_{n=n_0}^{\infty} \frac{1}{n^3} = \frac{1}{2}.$$  \hfill (4.5)

Therefore,

$$\lim_{n_0 \to \infty} \left\langle \frac{d\sigma^{\text{RR}}}{d\Omega_k} \right\rangle_{\Delta \omega} = \lim_{n_0 \to \infty} \frac{2n_0^3}{Z^2} \sum_{n=n_0}^{\infty} \frac{16Z^5v}{c^3} \left(\frac{1}{(v^2 + Z^2/n^2)^3}\right) \sin^2 \theta_k$$
Numerically, the RR cross sections \(d\sigma^{(\omega)}/d\Omega_k\) are calculated for a series of \(n\) (typically up to \(n \sim 16\)) and are subsequently fitted by a power law \(A_1(\theta_k)/n^3\) that is obeyed to high accuracy beyond \(n \approx 8\) [37]. From the result (4.6) it follows that \(d^2\sigma^{SWL}/d\omega d\Omega_k = A_1(\theta_k)/Z^2\). Since the formula \(Z^2/(2\pi^2)\) for the binding energy of high Rydberg states remains valid for heavy nuclei, this prescription can also be used in the relativistic case. (In Fig.4 below the additional factor \(10^3/27.21\) is included to convert atomic units into keV.)

Fig.3 shows the angular dependence of the emitted photons for the two cases \(E_{i,kin} = 180\) keV and 380 keV. Comparison is made between the partial-wave model, the DSM theory, the SM theory and experiment. It is seen that the SM cross sections are generally a factor of 2-3 too low (a fact well-known from previous investigations [24, 33] for high nuclear charge), the discrepancy increasing at the backward angles. As expected, the partial-wave theory describes experiment nicely, but this is also true for the DSM model at angles \(\theta_k \lesssim 120^\circ\). At the larger emission angles relativity plays a more and more important role (due to the increasing momentum transfer) such that the SM functions are no longer appropriate. Turning to the importance of screening (the partial-wave calculations are done for the neutral target as used in experiment, while the SM and DSM results are for a bare nucleus) we note that for \(E_{i,kin} \gtrsim 200\) keV the relevant electron-nucleus distances at the SWL (given by the inverse momentum transfer) lie within the \(K\)-shell radius, even in the forward hemisphere. Thus screening affects the normalization rather than the shape of the wavefunction [33]. In the angular regime pertaining to the total cross section, screening amounts to 5-10 percent at impact energies between 100 keV and 1 MeV [33, 31], being small at the backward angles and decreasing with energy [10, 24, 28]. So screening is at most of the same order as the numerical accuracy of the DSM results which justifies its neglect for all cases considered.

When the impact energy is further increased the cross section drops rapidly for \(\theta_k \gtrsim 20^\circ\) without much changing its overall shape. However, the photons are more and more focussed at very small angles, which even leads to an increase of the cross section at \(\theta_k = 0\) for \(E_{i,kin} \gtrsim 2\) MeV (Fig.4). This behaviour can be related to the dominant phase factor, \(e^{i(k_i-k)r}\), in the radiation matrix element (2.2). We have \(k_i c = \sqrt{E_i^2 - c^2}\) and in the SWL, \(kc = \omega = E_i - c^2\) such that \(k/k_i \rightarrow 1\) and \(k_i - k \rightarrow c\) for \(E_i \rightarrow \infty\) [33]. Therefore, at \(\theta_k = 0\), the phase \((k - k_i)\cos \theta\) tends to a constant (in \(k_i\)) with increasing \(E_i\) (at 2 MeV, \((k_i - k)/c = 0.9\)). Together with the prefactor \(\omega\) in (2.1), this leads to an increase of the cross section. However, for any small but finite \(\theta_k\) there exists some energy \(E_\theta\) such that for \(E_i > E_\theta\), \(|k_i - k|\) increases strongly (eventually to \(\infty\)), leading to a steep decrease of the cross section with energy.

Concerning the validity of the DSM theory we recall that the SM functions approach the exact functions for sufficiently large energies \(E_i\), provided \(r \gg Z\alpha/k_i\). For \(\theta_k = 0\), this condition can be translated into

\[
r \sim \frac{1}{|(k_i - k)\cos \theta|} \geq \frac{1}{(k_i - k)} \gg \frac{Z\alpha}{k_i} \tag{4.7}
\]

For \(E_{i,kin} = 2\) MeV, respectively 5 and 10 MeV, the ratio \(k_i/k_i - k\) is equal to 5.4, respectively 11.3 and 21.1. Thus for Au \((Z\alpha \approx 0.6)\) the SM initial-state function is reliable near and above 2 MeV at small angles (see also Fig.4).

In the backward regime, on the other hand, say \(\theta_k = 180^\circ\), the condition (4.7) has to be replaced by \((k_i + k)|\cos \theta| \ll k_i\). This holds only for polar angles close to 90\(^\circ\) and therefore the DSM model performs worse. From Fig.4 it follows that at 2 MeV there are still considerable deviations between the DSM and the partial-wave results for \(\theta_k\) beyond 60\(^\circ\). As concerns the SM results, the inadequacy of the approximate final threshold state (irrespective of \(E_i\)) prevents a better agreement with the DSM model when the collision energy is increased.

In order to get an estimate of the correction effects concerning nonorthogonality we have calculated the singly differential cross section \(S_{\omega} \equiv d\sigma/dE_f (= d\sigma/d\omega)\) by integrating over the photon solid angle, and have compared it to the respective cross section (termed \(S_1\)) when the transition operator is set to unity (i.e. in the absence of photons). For the Au target the ratio \(S_1/S_{\omega}\) is given by 0.0092 (for 180
included in Fig. 4 is the SM theory for photons carrying away only half the electron’s energy (\( \omega = E_{f,kin} = 5 \text{ MeV} \) where SM functions are appropriate except possibly at the largest angles). As compared to the SWL at 10 MeV, the corresponding cross section is enhanced at all angles and also shows the steep increase towards \( \theta_k = 0 \), while depending only weakly on angle beyond 140°.

5 Polarization correlations

The polarization correlations for bremsstrahlung are in detail specified by Tseng and Pratt [10], however using a reference frame in which the –axis is aligned with the photon momentum rather than with the collision velocity. Starting point is the representation of the differential cross section (2.1) in the following form, making use of the time-reversal invariance [10],

\[
d\sigma = \frac{1}{2} \, d\sigma_0 \left( 1 + C_{03}\zeta_3 + C_{11}\zeta_1 \xi_1 + C_{12}\zeta_1 \xi_2 + C_{20}\zeta_2 + C_{23}\zeta_2 \xi_3 \right. \\
\left. + C_{31}\zeta_1 \xi_1 + C_{32}\zeta_1 \xi_2 \right) \tag{5.1}
\]

where \( \xi \) and \( \zeta \) denote, respectively, the parameters for photon and electron (initial-state) polarization, \( d\sigma_0 \) is the differential cross section averaged over the initial spin of the electron and summed over the final electron spin and photon polarization. \( C_{ik}, i,k \in \{0,1,2,3\} \) are the nonvanishing correlation parameters. With \( e_\lambda \) from (2.4) for linear photon polarization we have

\[
\xi_1 = 2 \sin \varphi_\lambda \cos \varphi_\lambda, \quad \xi_2 = 0, \quad \xi_3 = 1 - 2 \sin^2 \varphi_\lambda, \tag{5.2}
\]

hence \( C_{12} \) and \( C_{32} \) do not occur. The electron spin direction \( n_s = (\zeta_1, \zeta_2, \zeta_3) \) is here defined with respect to the basis \( \zeta_1 = e_x, \quad \zeta_2 = -e_y, \quad \zeta_3 = -e_z \) in our coordinate system (i.e. \( \zeta_3 \) antiparallel to \( \mathbf{k}_i, \quad \zeta_2 \) aligned with \( \mathbf{k}_i \times \zeta_2 \)).

The Stokes parameters \( P_1 \) and \( P_2 \) are obtained from the geometry where the spin direction \( n_s \) lies in the scattering plane (\( \varphi_s = 0 \) in (2.4), respectively \( \zeta_2 = 0 \) in the above basis). In that case (5.1) reduces to

\[
d\sigma = \frac{1}{2} \, d\sigma_0 \left( 1 + C_{03}\zeta_3 + C_{11}\zeta_1 \xi_1 + C_{31}\zeta_1 \xi_1 \right). \tag{5.3}
\]

If we choose \( \varphi_\lambda \in \{0, \frac{\pi}{2}\} \) then \( \xi_1 \) vanishes while \( \xi_3 \in \{1, -1\} \). Thus we get

\[
P_1 \equiv C_{03} = \frac{d\sigma(\varphi_\lambda = 0) - d\sigma(\varphi_\lambda = 90°)}{d\sigma(\varphi_\lambda = 0) + d\sigma(\varphi_\lambda = 90°)} = \frac{d\sigma(e_{\lambda}^2) - d\sigma(e_{\lambda}^4)}{d\sigma(e_{\lambda}^2) + d\sigma(e_{\lambda}^4)}, \tag{5.3}
\]

\( P_1 \) is independent of \( \zeta_1 \) and \( \zeta_3 \) (respectively of \( \alpha_s \), the polar angle of \( n_s \), such that also for unpolarized electrons, \( P_1 \) is calculated from (5.3).

For obtaining \( P_2 \) (respectively \( C_{11} \) and \( C_{31} \)) we have to get rid of \( C_{03} \), so we take \( \varphi_\lambda \in \{45°, 135°\} \) where \( \xi_3 \) vanishes. \( P_2 \) is defined by

\[
P_2(\alpha_s) = \frac{d\sigma(\varphi_\lambda = 45°) - d\sigma(\varphi_\lambda = 135°)}{d\sigma(\varphi_\lambda = 45°) + d\sigma(\varphi_\lambda = 135°)} = C_{11}\zeta_1 + C_{31}\zeta_3. \tag{5.4}
\]

In contrast to \( P_1 \), \( P_2 \) does depend on \( \alpha_s \). It obeys the symmetry property \( P_2(\alpha_s + \pi) = -P_2(\alpha_s) \) since the augmentation of \( \alpha_s \) by \( \pi \) changes the sign of \( n_s \) (and hence of \( \zeta_1 \) and \( \zeta_3 \)).

The polarization correlation \( C_{11} \) results from (5.4) by choosing \( n_s = \zeta_1 \) and noting that \( \alpha_s = \frac{\pi}{2} \) corresponds to \( \zeta_1 = 1 \). In a similar way, setting \( n_s = \zeta_3 \) (with \( \alpha_s = 0 \) relating to \( \zeta_3 = -1 \)), \( C_{31} \) is obtained. Explicitly,

\[
P_{2\perp} \equiv P_2(90°) = C_{11} \\
P_{2\parallel} \equiv P_2(0) = -C_{31}. \tag{5.5}
\]
The remaining polarization correlations, $C_{20}$ and $C_{23}$, characterize the electron spin polarization perpendicular to the scattering plane with $\zeta_1 = \zeta_3 = 0$, corresponding to $\alpha_s = \frac{\pi}{2}$.

Then one gets from (5.1), $d\sigma = \frac{1}{2} d\sigma_0 (1 + C_{03} \zeta_3 + C_{20} \zeta_2 + C_{23} \zeta_3 \zeta_5)$. In order to eliminate $C_{03}$ we sum over the photon polarization, i.e., we add the differential cross sections obtained from $\varphi_\lambda = 0$ ($\Xi_1 = 1$) and from $\varphi_\lambda = \frac{\pi}{2}$ ($\Xi_1 = -1$). This leads to $\sum_\lambda d\sigma = d\sigma_0 (1 + C_{20} \zeta_2)$. Consequently, representing $n_s = \zeta_2$ by $\varphi_s = -\frac{\pi}{2}$ and $n_s = -\zeta_2$ by $\varphi_s = \frac{\pi}{2}$, the spin asymmetry is calculated from

$$A \equiv C_{20} = \sum_\lambda \frac{(d\sigma(\uparrow) - d\sigma(\downarrow))}{(d\sigma(\uparrow) + d\sigma(\downarrow))},$$

(5.6)

where $\uparrow$ and $\downarrow$ represent, respectively, the pairs $(\alpha_s, \varphi_s) = (\frac{\pi}{2}, -\frac{\pi}{2})$ and $(\frac{\pi}{2}, \frac{\pi}{2})$.

The last correlation parameter, $C_{23}$, is not directly accessible. Let us define, for each spin direction, the linear polarization according to formula (5.3),

$$P_1(\uparrow) = \frac{d\sigma_{\varphi=0}(\uparrow) - d\sigma_{\varphi=90^\circ}(\uparrow)}{d\sigma_0} = C_{03} + C_{23}$$

$$P_1(\downarrow) = \frac{d\sigma_{\varphi=0}(\downarrow) - d\sigma_{\varphi=90^\circ}(\downarrow)}{d\sigma_0} = C_{03} - C_{23}$$

(5.7)

with $d\sigma_0 = \frac{1}{2} \sum_\lambda (d\sigma(\uparrow) + d\sigma(\downarrow))$. This leads to

$$C_{23} = \frac{1}{2} [P_1(\uparrow) - P_1(\downarrow)].$$

(5.8)

Fig.5 shows the Stokes parameter $P_1$ for an impact energy of 10 MeV and photon energies between 3 and 10 MeV. From the investigation of [38] it follows that for $P_1$, the SM functions provide a satisfactory description if the kinetic energy is above 2 MeV, such that the application of the SM theory is basically justified. Away from the short-wavelength limit and for photon angles above $20^\circ$ the linear polarization is negative (which means that the photons are predominantly polarized perpendicular to the collision plane, a purely relativistic effect) and varies only weakly with $\theta_k$. However, there is a considerable overall rise of $P_1$ when $\omega$ is increased from 9 to 10 MeV. At very small angles $P_1$ varies strongly with $\omega$, showing a large negative peak for $\omega \lesssim \frac{1}{2} E_{i,kin}$, but a positive peak when the SWL is approached. The change of the forward maximum of $P_1$ to a minimum when $\omega$ is decreased was also found at lower impact energies (see Fig.10 of [10] for $E_{i,kin} = 0.5$ MeV). In the high-energy regime the forward maximum decreases with impact energy at the SWL; for $\omega = 0.9 E_{i,kin}$ even to a negative value (see Fig.1).

In Fig.6a the polarization correlations $P_2$, $A$ and $C_{23}$ are displayed for $E_{i,kin} = 10$ MeV and $\omega = 5$ MeV, using the Sommerfeld-Maue theory. It was derived by Tseng and Pratt [10] that $P_{2\perp} = -C_{23}$ near $\theta_k = 0$, and $P_{2\perp} = C_{23}$ near $\theta_k = 180^\circ$, which is clearly seen in the figure. However, as compared to the results for $\omega/E_{i,kin} = 0.5$ at an impact energy of 0.5 MeV [10, Fig.26], the regime where $P_{2\perp}$ and $C_{23}$ are approximately symmetric to each other extends to much larger angles ($\theta_k \lesssim 150^\circ$) with only a small region where the slopes of $P_{2\perp}$ and $C_{23}$ roughly agree ($\theta_k \gtrsim 170^\circ$). The most striking feature when $E_{i,kin}$ is increased from 0.5 to 10 MeV is the global decrease in modulus of the polarization correlations $P_2$ and $C_{23}$ (up to one order of magnitude). Again, there is the relativistic focussing of the extrema to the forward angles. An exception is the spin asymmetry $A$, the maximum of which is shifted to backward angles and has a similar value at 0.5 and 10 MeV.

In Fig.6b the same polarization correlations are plotted at the SWL, calculated within the DSM model. Since the emission of a 10 MeV photon requires very close collisions, relativity is extremely important and the polarization correlations are indeed much larger than for $\omega = 5$ MeV. Both $C_{23}$ and $P_{2\perp}$ exhibit a broad extremum in the forward hemisphere and an additional narrow minimum at angles close to $180^\circ$. As concerns the spin asymmetry $A$ it was predicted a long time ago, using a perturbative expansion, that $A$ depends linearly on $Z\alpha$ [51]. In fact, at $\omega = 10$ MeV (and a gold target) the maximum of $A$ is
\( \sim 0.6 \) which is close to \( Z \alpha = 0.58 \). Moreover, as follows from Fig. 7 where the spin asymmetry at the SWL is shown for impact energies between 2 and 10 MeV, the maximum of \( A \) is still increasing with \( E_i \) in this energy regime (whereas the minimum in the forward hemisphere gets shallower). This increase of \( A \) up to at least \( E_{i,kin} = 10 \) MeV is at variance with the conjecture of [51] that \( A \) should be largest for \( v/c \approx 0.6 \) (corresponding to \( E_{i,kin} \approx 130 \) keV). It should be noted that there are no literature results for \( A \) at the SWL. However, even if we fix the ratio \( \omega/E_{i,kin} = 0.75 \), then at 130 keV one has \( |A| \lesssim 0.14 \) at all photon angles [10], whereas the SM calculations at \( E_{i,kin} = 10 \) MeV (and the same ratio) predict \( A \approx 0.17 \) in its maximum near \( \theta_k = 140^\circ \).

6 Conclusion

We have investigated the photon angular distribution and the polarization correlations resulting from bremsstrahlung of highly relativistic spin-polarized electrons colliding with heavy ions such as gold. Particular emphasis was laid on the short-wavelength limit where the electron transfers all its kinetic energy to the photon. For this process the DSM theory was developed where the wavefunction of the incoming electron is described by a Sommerfeld-Maue function in place of an exact relativistic function. This approximation, valid above 5 MeV impact energy (except possibly at the largest photon angles) leads to a considerable reduction of computer time as compared to the relativistic partial-wave calculations, thus allowing for collision energies up to at least 10 MeV. The DSM model can readily be extended to a small region below the SWL by replacing the Bessel functions in (2.6) by the corresponding exact radial functions and by including some more final-state partial waves. The basic advantage of this model, the small number of partial waves, is, however, lost when photons with an energy much lower than the SWL are considered.

Our main concern was the improvement of the doubly differential cross section at the SWL as compared to the results from the commonly used Elwert-Haug theory. Indeed, for the two test cases \( E_{i,kin} = 180 \) and 380 keV where experimental data and partial-wave results are available, the DSM model performs well except for photon angles above 130°. This region of validity shrinks to smaller angles when the collision energy is increased to 2 MeV. Only beyond 5 MeV will the Sommerfeld-Maue function again perform well as conjectured from the results of [38].

We have also studied the dependence of the polarization correlations on photon energy and angle at 10 MeV and have compared with the corresponding results of Tseng and Pratt at 0.5 MeV, the highest collision energy considered by these authors for a heavy (gold) target. For \( P_1 \) we observe, similar to the elementary process of bremsstrahlung (i.e. when electrons and photons are detected simultaneously in a coplanar geometry [52]), that \( P_1 \) is closest to unity when the differential cross section has its maximum. The forward focussing at 10 MeV is also seen for \( P_2 \) and \( C_{23} \).

An exception is the spin asymmetry \( A \) which gets strongly focussed near \( \theta_k = 180^\circ \) when the collision energy is increased. While the other polarization correlations are subject to an overall decrease of modulus with collision energy beyond 2 MeV, the maximum of \( A \) increases with \( E_{i,kin} \), at least up to 10 MeV. At collision energies near 15 MeV and \( \theta_k \) near 180° the relevant distances will reach \( r = 1.3 \times 10^{-4} \) a.u. = 7 fm which is the radius of the Au nucleus. Thus \( A \) is a candidate for measuring nuclear size effects when \( E_{i,kin} > 10 \) MeV (see the predictions of [53] for the elastic backscattering of spin-polarized electrons).

Acknowledgments

It is a pleasure to thank S.Tashenov for stimulating this project, and A.Surzhykov for valuable comments and for providing new partial-wave results. I am also indebted to R.Pratt for many helpful remarks.

Fig. 1
Linear polarization $P_1$ of photons emitted with energy $\omega = 0.9 \ E_{1.\text{kin}}$ in $e$-Au collisions as a function of the collision energy $E_{1.\text{kin}} = E_1 - c^2$. For each $E_{1.\text{kin}}$, the photon angle is chosen such that $P_1$ has its maximum value (upper points and curves), respectively its minimum value (occurring at larger angles; lower points and curves). The broken and chain curves are present SM results for bare Au. The full line results from the analytic formula (7.1) with (6.23) of [7], valid in the forward regime only. The calculations of [8] (×) and [10] (×) result from the partial-wave model. Experimental results (near the extrema of $P_1$) are taken from [11] – [13].
Fig. 2
Sketch of the collision geometry. The $y$-axis and $e_{\lambda}$ point into the drawing plane (marked by the backside $\otimes$ of an arrow). $n^+_s$ is the projection of $n_s$ onto the $(x,z)$-plane.

Fig. 3
Doubly differential cross section for photon emission from collisions of 180 keV (a) and 380 keV (b) electrons with Au at the SWL ($\omega = 180$ keV respectively 380 keV) as a function of photon angle $\theta_k$. Shown are the results from the partial-wave model [8] (-----), the DSM theory (-----), the Sommerfeld-Maue theory (---) and experiment [50] (■).

Fig. 4
Doubly differential cross section for photon emission from collisions of 2 MeV (upper curves) and 10 MeV (lower curves) electrons with Au$^{79+}$ at the SWL as a function of photon angle $\theta_k$. ——, DSM model, ————, SM results. Included is the SM result for $E_{i,kin} = 10$ MeV, $\omega = 5$ MeV (---), as well as partial-wave results at 2 MeV (×) [37].
