

Morse actions of discrete groups on symmetric spaces

Michael Kapovich, Bernhard Leeb, Joan Porti

March 29, 2014

Abstract

We study the geometry and dynamics of discrete infinite covolume subgroups of higher rank semisimple Lie groups. We introduce and prove the equivalence of several conditions, capturing “rank one behavior” of discrete subgroups of higher rank Lie groups. They are direct generalizations of rank one equivalents to convex cocompactness. We also prove that our notions are equivalent to the notion of Anosov subgroup, for which we provide a closely related, but simplified and more accessible reformulation, avoiding the geodesic flow of the group. We show moreover that the Anosov condition can be relaxed further by requiring only non-uniform unbounded expansion along the (quasi)geodesics in the group.

A substantial part of the paper is devoted to the coarse geometry of these discrete subgroups. A key concept which emerges from our analysis is that of *Morse quasigeodesics* in higher rank symmetric spaces, generalizing the Morse property for quasigeodesics in Gromov hyperbolic spaces. It leads to the notion of *Morse actions* of word hyperbolic groups on symmetric spaces, i.e. actions for which the orbit maps are Morse quasiisometric embeddings, and thus provides a coarse geometric characterization for the class of subgroups considered in this paper. A basic result is a local-to-global principle for Morse quasigeodesics and actions. As an application of our techniques we show algorithmic recognizability of Morse actions and construct Morse “Schottky subgroups” of higher rank semisimple Lie groups via arguments not based on Tits’ ping-pong. Our argument is purely geometric and proceeds by constructing equivariant Morse quasiisometric embeddings of trees into higher rank symmetric spaces.

1 Introduction

This paper is motivated by the search for “geometrically nice” infinite covolume discrete groups of isometries of higher rank symmetric spaces, respectively, discrete subgroups of semisimple Lie groups with finite center. A reasonable class of such groups should be broad enough and at the same time manageable.

The class of groups considered in this paper can be viewed as groups with *rank one actions on higher rank symmetric spaces*, i.e. discrete subgroups of semisimple Lie groups which exhibit some rank one behavior. They are a direct generalization of *convex cocompact* subgroups of rank one Lie groups. The strength of the notion of convex cocompactness in rank one relies on a number of different characterizations in terms of geometry/dynamics (conical limit set), dynamics (expansion at the limit set, uniform convergence action on the limit set), coarse geometry (undistorted) and topology (existence of a natural compactification of the quotient locally symmetric space). Furthermore, for these subgroups one can prove results which are inaccessible or unavailable otherwise (e.g. topological or algebraic finiteness properties). In chapter 4, we will go through different characterizations of rank one convex cocompact groups.

In higher rank, some of these characterizations turn out to be too restrictive, and others too weak. For example, it was shown by Kleiner and Leeb [KL06] that convex cocompactness is too restrictive in higher rank, as it is satisfied only by few subgroups. On the other hand, undistortion is way too weak; for instance, undistorted subgroups can fail to be finitely presented. Thus, one is forced to look for alternative generalizations of convex cocompactness in

higher rank.

In this paper, we will consider, in the context of *weakly regular* discrete subgroups $\Gamma \subset G$ of semisimple Lie groups (with finitely many connected components and finite center), four notions generalizing convex cocompactness to higher rank:

- (i) conical (RCA) subgroups
- (ii) subgroups expanding at a (suitable) limit set
- (iii) asymptotically embedded subgroups
- (iv) Morse subgroups

Whereas (i)-(iii) are asymptotic (mostly dynamical) conditions, condition (iv) is coarse geometric. The Morse condition is a suitable strengthening of undistortedness in higher rank; the orbit quasigeodesics must satisfy an additional restriction which is a higher rank analogue of the Morse property for quasigeodesics in hyperbolic spaces. See below for the definitions.

A consequence of the equivalence (iii) \Leftrightarrow (iv) is the *structural stability* of asymptotically embedded subgroups, generalizing Sullivan's Structural Stability Theorem in rank one [Su]. Another consequence of this equivalence is that asymptotically embedded subgroups are undistorted and uniformly regular.

Furthermore, an important feature of the Morse condition (iv) is that it admits a *local* characterization. The localness of the Morse property implies that the space of Morse actions is open, and that Morse subgroups are algorithmically recognizable.

We illustrate our techniques by constructing Morse-Schottky actions of free groups on higher rank symmetric spaces. Unlike all previously known constructions, our proof does not rely on ping-pong, but is purely geometric and proceeds by constructing equivariant quasi-isometric embeddings of trees. The key step is the observation that a certain local *straightness* property for sufficiently spaced sequences of points in the symmetric space implies the global Morse property. This observation is also at the heart of the proof of the local-to-global principle for Morse actions.

An advantage of the notion of conicality/expansivity over the notions of asymptotic embeddedness and Morse is that it does not a priori assume that the subgroup is word hyperbolic as an abstract group. For example, uniform lattices in semisimple Lie groups satisfy this property. Thus, the conicality condition can serve as an ingredient in a general theory of "geometric niceness" in higher rank which includes groups which are not (relatively) hyperbolic.

In our paper [KLP], we study the dynamics of weakly regular antipodal discrete subgroups acting on the partial flag manifolds associated to semisimple Lie groups. We construct domains of discontinuity in general. Furthermore, we prove cocompactness of actions under the additional assumption of expansivity, equivalently, conicality using some of the discussion in this paper. The latter results can be regarded as a weak form of cocompactness for the action on the domain of discontinuity at infinity in rank one.

We prove (section 6.5.2, Theorem 6.57) that our characterizations (i)-(iv) are equivalent to the notion of *Anosov representation* (subgroup) introduced by Labourie [La06] and developed

further by Guichard and Wienhard [GW]. In section 6.5.1, we also give a closely related, but simplified and more accessible reformulation of the Anosov property. Our definition involves only an expansion property for the group action on the flag manifold and avoids the notion of expansion/contraction of flows on bundles. In particular, it avoids using the geodesic flow for hyperbolic groups (whose construction is highly involved for groups which do not arise as the fundamental group of a closed negatively curved Riemannian manifold). In section 6.5.2, we present a further relaxation of our version of the Anosov condition, by requiring only non-uniform unbounded expansion along quasigeodesics in Γ . Nevertheless, we show that the resulting class of subgroups remains the same (Theorem 6.57).

While our methods are independent of the ones in [La06, GW], it was known before that Anosov subgroups are undistorted ([GW, Theorem 5.3]), uniformly regular ([GW, Proposition 3.16]), and that Anosov representations are structurally stable ([GW, Theorem 5.13]).

In addition to the equivalent conditions mentioned above, we also introduce a notion of *boundary embeddedness* for discrete subgroups which are word hyperbolic as abstract groups. It is a priori a weakening of asymptotic embeddedness, as it only requires an antipodal equivariant embedding of the Gromov boundary into the flag manifold. Here, antipodality means that distinct points go to opposite simplices. Boundary embeddedness constitutes the non-dynamical part of the definition of Anosov subgroup, omitting the expansivity. We show that boundary embeddedness is equivalent to asymptotic embeddedness in the regular case (see Proposition 6.24).

We now describe in more detail some of the concepts and results discussed above.

Let $X = G/K$ be a symmetric space of noncompact type. Of primary importance to us will be the visual boundary $\partial_\infty X$ and the fact that it carries a natural structure as a spherical building $\partial_{Tits} X$. We recall that the visual limit set $\Lambda(\Gamma) \subset \partial_\infty X$ of a discrete subgroup $\Gamma \subset G$ is the set of accumulation points of an(y) Γ -orbit $\Gamma x \subset X$.

Weak regularity of discrete subgroups is an asymptotic condition regarding the directions of segments connecting orbit points. It is defined with respect to a fixed face τ_{mod} of the model Weyl chamber σ_{mod} associated to G and X . The condition of τ_{mod} -regularity is a relaxation of uniform τ_{mod} -regularity which requires that all limit points of Γ are τ_{mod} -regular, see Definition 5.6. In the case when $\tau_{mod} = \sigma_{mod}$, uniform regularity simply means that all limit points of Γ are interior points of chambers in the Tits building.

The τ_{mod} -regularity of a discrete subgroup $\Gamma \subset G$ can be read off its dynamics at infinity, namely it is equivalent to a contraction-expansion property of the Γ -action on the partial flag manifold

$$\text{Flag}(\tau_{mod}) = G/P_{\tau_{mod}}$$

associated to G and τ_{mod} , generalizing convergence dynamics in rank one, see section 5.2.

For τ_{mod} -regular subgroups and, more generally, for subgroups containing diverging τ_{mod} -regular sequences, we have a τ_{mod} -*limit set*

$$\Lambda_{\tau_{mod}}(\Gamma) \subset \text{Flag}(\tau_{mod}).$$

In the uniformly τ_{mod} -regular case, the τ_{mod} -limit set is the natural projection of $\Lambda(\Gamma)$ to $\text{Flag}(\tau_{mod})$. Furthermore, in the uniformly regular case, $\Lambda_{\sigma_{mod}}(\Gamma)$ is the set of chambers which contain ordinary limit points. We will refer to points in $\Lambda_{\tau_{mod}}(\Gamma)$ as *limit simplices* or *limit flags*. We call Γ τ_{mod} -non-elementary if it has at least three limit flags of type τ_{mod} .

Definition 1.1 (Antipodal). A τ_{mod} -regular discrete subgroup $\Gamma \subset G$ is called τ_{mod} -antipodal, if any two distinct limit simplices in $\Lambda_{\tau_{mod}}(\Gamma)$ are opposite.

The notion of conicality of limit simplices is due to Albuquerque [Al, Def. 5.2]. For simplicity, we give it here only in the regular case and refer the reader to Definition 6.1 for the general case.

Definition 1.2 (Conicality). A σ_{mod} -regular discrete subgroup $\Gamma \subset G$ is called σ_{mod} -conical if for every limit chamber $\sigma \in \Lambda_{\sigma_{mod}}(\Gamma)$ there exists a sequence $\gamma_n \rightarrow \infty$ in Γ such that for a(ny) point $x \in X$ the sequence of orbit points $\gamma_n x$ is contained in a tubular neighborhood of the euclidean Weyl chamber $V(x, \sigma)$ with tip x and asymptotic to σ .

Definition 1.3 (RCA). A discrete subgroup $\Gamma \subset G$ is called τ_{mod} -RCA if it is τ_{mod} -regular, τ_{mod} -conical and τ_{mod} -antipodal.

Following Sullivan [Su], we call a subgroup expanding at infinity if its action on the appropriate partial flag manifold is expanding at the limit set. More precisely:

Definition 1.4 (Expanding). We call a τ_{mod} -regular discrete subgroup $\Gamma \subset G$ τ_{mod} -expanding at the limit set if for every limit flag in $\Lambda_{\tau_{mod}}(\Gamma)$ there exists a neighborhood U in $\text{Flag}(\tau_{mod})$ and an element $\gamma \in \Gamma$ which is uniformly expanding on U , i.e. for some constant $c > 1$ and all $\tau_1, \tau_2 \in U$ we have:

$$d(\gamma\tau_1, \gamma\tau_2) \geq c \cdot d(\tau_1, \tau_2)$$

Here, the distance d is induced by a Riemannian background metric on the flag manifold.

Definition 1.5 (Asymptotically embedded). We call a τ_{mod} -antipodal τ_{mod} -regular discrete subgroup $\Gamma \subset G$ τ_{mod} -asymptotically embedded if Γ is word hyperbolic and there exists a Γ -equivariant homeomorphism

$$\alpha : \partial_\infty \Gamma \xrightarrow{\cong} \Lambda_{\tau_{mod}}(\Gamma) \subset \text{Flag}(\tau_{mod})$$

of its Gromov boundary onto its τ_{mod} -limit set.

For simplicity, we define the Morse property only in the regular case, see Definitions 7.14, 7.23 and 7.30 for the general case.

Definition 1.6 (Morse). (i) A uniformly regular quasigeodesic ray in X is called σ_{mod} -Morse if it converges to a chamber at infinity in uniform conical fashion, compare Definition 1.2.

(ii) An isometric action $\rho : \Gamma \curvearrowright X$ of a word hyperbolic group Γ is called σ_{mod} -Morse if its orbit map sends uniform quasigeodesic rays in Γ to uniformly σ_{mod} -Morse quasigeodesic rays in X . In this case the image $\rho(\Gamma)$ will be called a σ_{mod} -Morse subgroup.

It follows immediately from the definition that Morse actions are properly discontinuous and Morse subgroups are discrete and undistorted.

The first main result of this paper is (see Theorems 6.16, 6.57 and 7.35):

Theorem 1.7 (Equivalence). *For τ_{mod} -non-elementary τ_{mod} -regular discrete subgroups $\Gamma \subset G$ the following properties are equivalent:*

1. Γ is τ_{mod} -RCA.
2. Γ is τ_{mod} -antipodal and its action on $\text{Flag}(\tau_{\text{mod}})$ is expanding at $\Lambda_{\tau_{\text{mod}}}(\Gamma)$.
3. Γ is τ_{mod} -asymptotically embedded.
4. Γ is τ_{mod} -Morse.
5. Γ is τ_{mod} -Anosov.

Whereas properties 3-5 include that Γ is word hyperbolic, it follows that subgroups having property 1 or 2 must be word hyperbolic.

Among the consequences of this theorem are (see Theorem 6.33):

Theorem 1.8 (Undistortedness and uniform regularity). *A subgroup $\Gamma \subset G$ satisfying one of the equivalent properties 1-5 is τ_{mod} -uniformly regular and undistorted.*

We recall that quasigeodesics in Gromov hyperbolic spaces can be recognized locally by looking at sufficiently large finite pieces. Our second main theorem is an analogous result for Morse quasigeodesics in symmetric spaces and, as a consequence, for Morse actions. Morse actions can be recognized locally by looking at the image of sufficiently large balls in the group under the orbit map (see Theorem 7.26):

Theorem 1.9 (Local-to-global). *For a word hyperbolic group Γ , locally τ_{mod} -Morse actions $\Gamma \curvearrowright X$ (for suitable parameters) are τ_{mod} -Morse actions.*

As a consequence of the localness and equivalence theorems, we obtain (see Theorems 7.33 and 7.36):

Theorem 1.10 (Openness of the space of Morse actions). *For a word hyperbolic group Γ , the subset of τ_{mod} -Morse actions is open in $\text{Hom}(\Gamma, G)$.*

Theorem 1.11 (Structural stability). *Let Γ be word hyperbolic. Then for τ_{mod} -Morse actions $\rho : \Gamma \curvearrowright X$, the boundary embedding α_ρ depends continuously on the action ρ .*

Thus, actions sufficiently close to a faithful Morse action are again discrete and faithful.

The localness implies furthermore, that Morse actions are algorithmically recognizable (see section 7.7):

Theorem 1.12 (Algorithmic recognition of Morse actions). *Let Γ be word hyperbolic. Then there exists an algorithm whose inputs are homomorphisms $\rho : \Gamma \rightarrow G$ (defined on generators of Γ) and which terminates if and only if ρ defines a τ_{mod} -Morse action $\Gamma \curvearrowright X$.*

If the action is not Morse, the algorithm runs forever. We do not know if there is an algorithm which recognizes non-Morse actions. Note, that even in hyperbolic 3-space no algorithm is known which recognizes that a finitely generated group is not convex cocompact.

Organization of the paper. In section 2 we review basic definitions from the theory of symmetric spaces and spherical buildings. We also prove some results on geometry of such spaces, including geometry of parallel sets and associated decompositions of X , cones in X over certain subsets of $\partial_\infty X$ and dynamics of transvections of X . In section 3 we discuss several standard concepts of topological dynamics, namely, convergence actions, expansivity and conical limit points. In section 4 we give a list of equivalent definitions of convex cocompact subgroups of rank one Lie groups. In section 5 we introduce several key asymptotic notions describing geometry of discrete groups, such as regularity and uniform regularity, various limit sets as well as antipodality and conicality of limit sets in partial flag manifolds. In section 6 we prove the equivalence of the first three items in Theorem 1.7 and establish some fundamental properties of asymptotically embedded groups which lead to the concept of Morse quasigeodesics and Morse actions. We conclude the section by discussing the Anosov condition. The notions of Morse quasigeodesics and actions are discussed in detail in section 7. In that section, among other things, we establish local-to-global principles, prove Theorem 1.7 and show that Morse actions are structurally stable and algorithmically recognizable. We also construct Morse-Schottky actions of free groups on symmetric spaces.

2 Geometric preliminaries

In this section we collect some standard material on Coxeter complexes, the geometry of non-positively curved symmetric spaces and associated spherical Tits buildings; we refer the reader to [KL98] and [Le] for more detailed discussion of symmetric spaces and buildings. We also prove some new results on the geometry of parallel sets and cones in symmetric spaces.

We start with some general notations:

A *tubular neighborhood* of a subset A of a metric space X is an open r -neighborhood of A in X for some $r > 0$, i.e. the set

$$N_r(A) = \{x \in X : d(x, A) < r\}.$$

We will use the notation

$$B(a, r) = \{x \in X : d(x, a) < r\}$$

and

$$\bar{B}(a, r) = \{x \in X : d(x, a) \leq r\}$$

for the open and, respectively, closed r -ball, centered at a .

A *geodesic* in a metric space X is an isometric embedding from a (possibly infinite) interval $I \subset \mathbb{R}$ into X . In the context of finitely generated groups Γ equipped with word metrics we will also sometimes use the notion of *discrete geodesics*, which are isometric maps

$$\gamma : I \rightarrow G$$

where I is an interval (possibly infinite) in \mathbb{Z} . Similarly, we will be talking about *discrete quasigeodesics* whose domains are intervals in \mathbb{Z} .

Definition 2.1. For a diffeomorphism $\Phi : M \rightarrow M$ of a Riemannian manifold M we define the *expansion factor* $\epsilon(\Phi, x)$ at a point $x \in M$ as

$$\epsilon(\Phi, x) = \inf_{v \in T_x M - \{0\}} \frac{\|d\Phi(v)\|}{\|v\|} = \|(d\Phi_x)^{-1}\|^{-1}.$$

The *exponential expansion factor* of Φ at x is defined as $\log(\epsilon(\Phi, x))$.

2.1 Coxeter complexes

A *spherical Coxeter complex* is a pair (S, W) consisting of a unit sphere S in a Euclidean vector space V and a finite group W which acts isometrically on S and is generated by reflections at hyperplanes. We will use the notation \angle for the angular metric on S . Throughout the paper, we assume that W does not fix a point in S and is associated with a root system R . Spherical Coxeter complexes will occur as *model apartments* of spherical buildings, mostly of Tits boundaries of symmetric spaces, and will in this context usually be denoted by a_{mod} .

A *wall* m_ρ in S is the fixed point set of a hyperplane reflection ρ in W . An *half-apartment* in S is a closed hemisphere bounded by a wall. A point $\xi \in S$ is called *singular* if it belongs to a wall and *regular* otherwise.

The action $W \curvearrowright S$ determines on S a structure as a simplicial complex whose facets, called *chambers*, are the closures of the connected components of

$$S - \bigcup_{\rho} m_\rho$$

where the union is taken over all reflections ρ in W . We will refer to the simplices in this complex as *faces*. (If one allows fixed points for W on S , then S carries only a structure as a cell complex.) Codimension one faces of this complex are called *panels*. The *interior* $\text{int}(\tau)$ of a face τ is the complement in τ to the union of walls not containing τ . The interiors $\text{int}(\tau)$ are called *open simplices* in (S, W) . A geodesic sphere in S is called *simplicial* if it equals an intersection of walls.

The chambers are fundamental domains for the action $W \curvearrowright S$. We define the *spherical model Weyl chamber* as the quotient $\sigma_{mod} = S/W$. The natural projection $\theta : S \rightarrow \sigma_{mod}$ restricts to an isometry on every chamber.

It is convenient, and we will frequently do so, to identify σ_{mod} with a chamber in S (traditionally called the *positive chamber*). An important elementary property of the chamber σ_{mod} is that its diameter (with respect to the spherical metric) is $\leq \frac{\pi}{2}$.

Given a face τ_{mod} of σ_{mod} , we define the subgroup $W_{\tau_{mod}} \subset W$ as the stabilizer of τ_{mod} in W . An identification of σ_{mod} with a chamber $\sigma \subset S$ determines a generating set of W , namely the reflections at the walls bounding σ_{mod} , and hence a word metric on W ; the longest element with respect to this metric is denoted w_0 . This element sends σ_{mod} to the opposite chamber in S . We say that two points $\xi, \hat{\xi} \in S$ are *Weyl antipodes* if $\hat{\xi} = w_0\xi$. We define the *standard involution* (also known as the *Cartan involution*)

$$\iota = \iota_S : S \rightarrow S$$

as the composition $-w_0$. This involution preserves σ_{mod} and equals the identity if and only if $-\text{id}_S \in W$ because then $w_0 = -\text{id}_S$.

A point ξ in S is called a *root* if the hemisphere centered at ξ is simplicial, equivalently, is bounded by a wall. Every root point ξ defines a certain linear functional $\alpha_\xi \in V^*$ on the Euclidean vector space V containing S as the unit sphere; this linear functional is also called root. The kernel of α_ξ is the hyperplane in V which intersects S along the wall defined by ξ . The set of roots in V^* is denoted by R and called the *root system* associated with the Coxeter complex (S, W) . We refer the reader to [Bou] for details.

Suppose that S is identified with the sphere at infinity of a Euclidean space F , $S \cong \partial_\infty F$, where $\partial_\infty F$ is equipped with the angular metric. For a chamber $\sigma \subset S$ and a point $x \in F$ we define the *Weyl sector* $V(x, \sigma) \subset F$ as the cone over σ with tip x , that is, as the union of rays emanating from x and asymptotic to σ .

After fixing an origin $o \in F$ the group W lifts to a group of isometries of F fixing o . The sectors $V(o, \sigma)$ are then fundamental domains for the action of $W \curvearrowright F$.

We define the *euclidean model Weyl chamber* as the quotient $V_{mod} = F/W$; we will also denote it by Δ or Δ_{euc} . It is canonically isometric to the complete euclidean cone over σ_{mod} . The natural projection $F \rightarrow V_{mod}$ restricts to an isometry on the sector $V(o, \sigma)$ for every chamber $\sigma \subset S$. Furthermore, for a closed subset $\bar{A} \subset \sigma_{mod}$ we define $V(0, \bar{A}) \subset V_{mod}$ as the complete cone over \bar{A} with tip 0. In particular, a face $\tau_{mod} \subset \sigma_{mod}$ corresponds to a face $V(0, \tau_{mod})$ of V_{mod} .

We define the Δ -valued distance function or Δ -distance d_Δ on F by

$$d_\Delta(x, y) = \text{proj}(y - x) \in \Delta$$

where $\text{proj} : F \rightarrow F/W \cong \Delta$ is the quotient map. Note the symmetry property

$$d_\Delta(x, y) = \iota_\Delta d_\Delta(y, x) \tag{2.2}$$

where ι_Δ denotes the isometric involution of Δ induced by ι_S . The Weyl group is precisely the group of isometries for the Δ -valued distance on F_{mod} which fix the origin.

2.2 Hadamard manifolds

In this section only, X denotes a Hadamard manifold, i.e. a simply connected complete Riemannian manifold with nonpositive sectional curvature. We will use the notation $\text{Isom}(X)$ for the full isometry group of X .

Any two points in X are connected by a unique geodesic segment. We will use the notation xy for the oriented geodesic segment connecting x to y and parameterized with unit speed. We will be treating geodesic segments, geodesic rays and complete geodesics as isometric maps of intervals to X ; we sometime will abuse the terminology and identify geodesics and their images.

We will denote by $\angle_x(y, z)$ the angle between the geodesic segments xy and xz at the point x . For $x \in X$ we let $\Sigma_x X$ denote the *space of directions* of X at x , i.e. the unit sphere in the tangent space $T_x X$, equipped with the angle metric.

The *ideal* or *visual boundary* of X , denoted $\partial_\infty X$, is the set of asymptote classes of geodesic rays in X , where two rays are *asymptotic* if and only if they have finite Hausdorff distance. Points in $\partial_\infty X$ are called *ideal points*. For $\xi \in \partial_\infty X$ and $x \in X$ we denote by $x\xi$ the geodesic ray emanating from x and asymptotic to ξ , i.e. representing the ideal point ξ . For $x \in X$ we have a natural map

$$\log_x : \partial_\infty X \rightarrow \Sigma_x X$$

sending $\xi \in \partial_\infty X$ to the velocity vector at x of the geodesic ray $x\xi$. The *cone* or *visual topology* on $\partial_\infty X$ is characterized by the property that all the maps \log_x are homeomorphisms; with respect to this topology, $\partial_\infty X$ is homeomorphic to the sphere of dimension $\dim(X) - 1$. The visual topology extends to $\bar{X} = X \cup \partial_\infty X$ as follows: A sequence (x_n) converges to an ideal point $\xi \in \partial_\infty X$ if the sequence of geodesic segments xx_n emanating from some (any) base point x converges to the ray $x\xi$ pointwise (equivalently, uniformly on compacts in \mathbb{R}). This topology makes \bar{X} into a closed ball. We define the visual boundary of a subset $A \subset X$ as the set $\partial_\infty A = \bar{A} \cap \partial_\infty X$ of its accumulation points at infinity.

The ideal boundary $\partial_\infty X$ carries the natural *Tits (angle) metric* \angle_{Tits} , defined as

$$\angle_{Tits}(\xi, \eta) = \sup_{x \in X} \angle_x(\xi, \eta)$$

where $\angle_x(\xi, \eta)$ is the angle between the geodesic rays $x\xi$ and $x\eta$. The *Tits boundary* $\partial_{Tits} X$ is the metric space $(\partial_\infty X, \angle_{Tits})$. The Tits metric is lower semicontinuous with respect to the visual topology and, accordingly, the *Tits topology* induced by the Tits metric is finer than the visual topology. It is discrete if there is an upper negative curvature bound, and becomes nontrivial if flat directions occur. For instance, the Tits boundary of flat r -space is the unit $(r-1)$ -sphere, $\partial_{Tits} \mathbb{R}^r \cong S^{r-1}(1)$. An isometric embedding $X \rightarrow Y$ of Hadamard spaces induces an isometric embedding $\partial_{Tits} X \rightarrow \partial_{Tits} Y$ of Tits boundaries.

A subset A of $\partial_{Tits} X$ is called *convex* if for any two points $\xi, \eta \in A$ with $\angle_{Tits}(\xi, \eta) < \pi$, the (unique) geodesic $\xi\eta$ connecting ξ and η in $\partial_{Tits} X$ is entirely contained in A .

Let $\xi \in \partial_\infty X$ be an ideal point. For a unit speed geodesic ray $\rho : [0, +\infty) \rightarrow X$ asymptotic

to ξ one defines the *Busemann function* b_ξ on X as the uniform monotonic limit

$$b_\xi(x) = \lim_{t \rightarrow +\infty} (d(x, \rho(t)) - t).$$

Altering the ray ρ changes b_ξ by an additive constant. Along the ray we have

$$b_\xi(\rho(t)) = -t.$$

The Busemann function b_ξ is convex, 1-Lipschitz and measures the relative distance from ξ . The sublevel sets

$$Hb_{\xi,x} = \{b_\xi \leq b_\xi(x)\} \subset X$$

are called (closed) *horoballs centered at ξ* . Horoballs are convex. The ideal boundaries of horoballs are the closed $\frac{\pi}{2}$ -balls at infinity with respect to the Tits metric,

$$\partial_\infty Hb_{\xi,x} = \{\angle_{Tits}(\xi, \cdot) \leq \pi/2\} \subset \partial_\infty X.$$

Busemann functions are *asymptotically linear* along rays; if $\gamma : [0, +\infty) \rightarrow X$ is a unit speed geodesic ray asymptotic to $\eta \in \partial_\infty X$, $\gamma(+\infty) = \eta$, then

$$\lim_{t \rightarrow \infty} \frac{b_\xi(\gamma(t))}{t} = -\cos \angle_{Tits}(\xi, \eta).$$

This limit is called the *asymptotic slope* of b_ξ at η . In particular, rays asymptotic to η enter horoballs centered at ideal points ξ with $\angle_{Tits}(\xi, \eta) < \frac{\pi}{2}$.

2.3 Symmetric spaces of noncompact type

The standard references for this and the following section are [Eb] and [H]. Our treatment of this standard material is more geometric than the one presented in these books.

A symmetric space, denoted by X throughout this paper, is said to be of *noncompact type* if it is nonpositively curved, simply connected and has no Euclidean factor. In particular, it is a Hadamard manifold. We will identify X with the quotient G/K where G is a semisimple Lie group acting isometrically and transitively on X , and K is a maximal compact subgroup of G . We will assume that G is commensurable with the isometry group $\text{Isom}(X)$ in the sense that we allow finite kernel and cokernel for the natural map $G \rightarrow \text{Isom}(X)$. In particular, the image of G in $\text{Isom}(X)$ contains the identity component $\text{Isom}(X)_o$. The Lie group G carries a natural structure as a real algebraic group.

A *point reflection* (confusingly, also known as a *Cartan involution*) at a point $x \in X$ is an isometry σ_x which fixes x and has differential $-\text{id}_{T_x X}$ in x . In a symmetric space, point reflections exist in all points (by definition). A *transvection* of X is an isometry which is the product $\sigma_x \sigma_{x'}$ of two point reflections; it preserves the oriented geodesic through x and x' and the parallel vector fields along it. The transvections preserving a unit speed geodesic $c(t)$ form a one parameter subgroup (T_t^c) of $\text{Isom}(X)_o$ where T_t^c denotes the transvection mapping $c(s) \mapsto c(s + t)$. A nontrivial isometry ϕ of X is called *axial* if it preserves a geodesic l and

shifts along it. (It does not have to be a transvection.) The geodesic l is called an *axis* of ϕ . Axes are in general not unique. They are parallel to each other.

A *flat* in X is a totally geodesic flat submanifold, equivalently, a convex subset isometric to a Euclidean space. A maximal flat in X is a flat which is not contained in any larger flat; we will use the notation F for maximal flats. The group $\text{Isom}(X)_o$ acts transitively on the set of maximal flats; the common dimension of maximal flats is called the *rank* of X . The space X has rank one if and only if it has strictly negative sectional curvature.

A maximal flat F is preserved by all transvections along geodesic lines contained in it. In general, there exist nontrivial isometries of X fixing F pointwise. The subgroup of isometries of F which are induced by elements of G is isomorphic to a semidirect product $\mathbb{R}^r \rtimes W$, where r is the rank of X . The subgroup \mathbb{R}^r acts simply transitively on F by translations. The linear part W is a finite reflection group, called the *Weyl group* of G and X . Since maximal flats are equivalent modulo G , the action $W \curvearrowright F$ is well-defined up to isometric conjugacy.

We will think of the Weyl group as acting on a *model flat* $F_{mod} \cong \mathbb{R}^r$ and on its ideal boundary sphere at infinity, the *model apartment* $a_{mod} = \partial_{Tits} F_{mod} \cong S^{r-1}$. The pair (a_{mod}, W) is the *spherical Coxeter complex* associated with X . We identify the spherical model Weyl chamber σ_{mod} with a (fundamental) chamber in the model apartment, $\sigma_{mod} \subset a_{mod}$. Accordingly, we identify the *euclidean model Weyl chamber* V_{mod} with the sector in F_{mod} with tip in the origin and ideal boundary σ_{mod} , $V_{mod} \subset F_{mod}$.

The Δ -valued distance naturally extends from F_{mod} to X because every pair of points lies in a maximal flat. In order to define the distance $d_\Delta(x, y)$ of two points $x, y \in X$ one chooses a maximal flat F containing x, y and identifies it isometrically with F_{mod} while preserving the types of points at infinity. The resulting quantity $d_\Delta(x, y)$ is independent of the choices. We refer the reader to [KLM] for the detailed discussion of *metric properties* of d_Δ .

For every maximal flat $F \subset X$, we have a Tits isometric embedding $\partial_\infty F \subset \partial_\infty X$ of its ideal boundary sphere. There is an identification $\partial_\infty F \cong a_{mod}$ with the model apartment, unique up to composition with elements in W . The Coxeter complex structure on a_{mod} induces a simplicial structure on $\partial_\infty F$. The ideal boundaries of maximal flats cover $\partial_\infty X$ because every geodesic ray in X is contained in a maximal flat. Moreover, their intersections are simplicial. One thus obtains a G -invariant piecewise spherical *simplicial structure* on $\partial_\infty X$ which makes $\partial_\infty X$ into a *spherical building* and, also taking into account the visual topology, into a topological spherical building. It is called the *spherical* or *Tits building* associated to X . The Tits metric is the path metric with respect to the piecewise spherical structure. We will refer to the simplices as *faces*.

The ideal boundaries $\partial_\infty F \subset \partial_\infty X$ of the maximal flats $F \subset X$ are precisely the *apartments* with respect to the spherical building structure at infinity, which in turn are precisely the convex subsets isometric to the unit $(r - 1)$ -sphere with respect to the Tits metric. Any two points in $\partial_\infty X$ lie in a common apartment.

The action $G \curvearrowright \partial_\infty X$ on ideal points is not transitive if X has rank ≥ 2 . Every G -orbit meets every chamber exactly once. The quotient can be identified with the spherical model

chamber, $\partial_\infty X/G \cong \sigma_{mod}$. We call the projection

$$\theta : \partial_\infty X \rightarrow \partial_\infty X/G \cong \sigma_{mod}$$

the *type* map. It restricts to an isometry on every chamber $\sigma \subset \partial_\infty X$. We call the inverse $\kappa_\sigma = (\theta|_\sigma)^{-1} : \sigma_{mod} \rightarrow \sigma$ the (*chamber*) *chart* for σ . Consequently, θ restricts to an isometry on every face $\tau \subset \partial_\infty X$. We call $\theta(\tau) \subset \sigma_{mod}$ the *type* of the face τ and $\kappa_\tau = (\theta|_\tau)^{-1} : \theta(\tau) \rightarrow \tau$ its *chart*. We define the *type* of an ideal point $\xi \in \partial_\infty X$ as its image $\theta(\xi) \in \sigma_{mod}$. A point $\xi \in \partial_\infty X$ is called *regular* if its type is an interior point of σ_{mod} , and *singular* otherwise. We denote by $\partial_\infty^{reg} X \subset \partial_\infty X$ the set of regular ideal boundary points. A point $\rho \in \partial_{Tits} X$ is said to be of *root type* if $\theta(\rho)$ is a root in $\sigma_{mod} \subset S$. Equivalently, the closed $\frac{\pi}{2}$ -ball centered at ρ (with respect to the Tits metric) is simplicial, i.e. is a simplicial subcomplex of $\partial_{Tits} X$.

A geodesic segment xy in X is called *regular* if $x \neq y$ and for the unique geodesic ray $x\xi$ containing xy the point $\xi \in \partial_{Tits} X$ is regular. Equivalently, the vector $d_\Delta(x, y)$ belongs to the interior of V_{mod} .

Two ideal points $\xi, \eta \in \partial_\infty X$ are called *antipodal* if $\angle_{Tits}(\xi, \eta) = \pi$.

We say that two simplices $\tau_1, \tau_2 \subset \partial_\infty X$ are *opposite* (or *antipodal*) *with respect to a point* $x \in X$ if $\tau_2 = \sigma_x \tau_1$, where σ_x is the reflection at the point x . We say that two simplices $\tau_1, \tau_2 \subset \partial_\infty X$ are *opposite* (or *antipodal*) if they are opposite simplices in the apartments containing both of them, equivalently, if every interior point of τ_1 has an antipode in the interior of τ_2 and vice versa, equivalently, if they are opposite with respect to some point $x \in X$. Their types are then related by $\theta(\tau_2) = \iota(\theta(\tau_1))$. We will frequently use the notation $\tau, \hat{\tau}$ and τ_+, τ_- for antipodal simplices.

One can quantify the antipodality of simplices of ι -invariant type $\tau_{mod} \subset \sigma_{mod}$ as follows: Pick an ι -invariant type $\bar{\zeta}$ in the interior of τ_{mod} , $\iota(\bar{\zeta}) = \bar{\zeta}$. Given two simplices τ_+, τ_- in $\partial_{Tits} X$ of type τ_{mod} and a point $x \in X$ define the ζ -*angle*

$$\angle_x^\zeta(\tau_-, \tau_+) = \angle_x(\xi_-, \xi_+), \quad (2.3)$$

where $\xi_\pm \in \tau_\pm$ are such that $\theta(\xi_\pm) = \bar{\zeta}$. Similarly, define the ζ -*Tits angle*

$$\angle_{Tits}^\zeta(\tau_-, \tau_+) = \angle_x^\zeta(\tau_-, \tau_+), \quad (2.4)$$

where x belongs to a flat $F \subset X$ such that $\tau_-, \tau_+ \subset \partial_{Tits} F$. Then simplices τ_\pm (of the same type) are antipodal iff

$$\angle_{Tits}^\zeta(\tau_-, \tau_+) = \pi$$

for some, equivalently, every, choice of ζ as above.

A pair of opposite chambers σ_+ and σ_- is contained in a unique apartment, which we will denote by $a(\sigma_+, \sigma_-)$; the apartment $a(\sigma_+, \sigma_-)$ is the ideal boundary of a unique maximal flat $F(\sigma_+, \sigma_-)$ in X .

For a point $x \in X$ and a simplex $\tau \subset \partial_\infty X$ we define the (*Weyl*) *sector* $V = V(x, \tau) \subset X$ as the union of rays $x\xi$ for all ideal points $\xi \in \tau$. It is contained in a flat. (Thus, Weyl sectors in X are isometric images of Weyl sectors $V(0, \tau_{mod}) \subset V_{mod}$ under isometric embeddings

$F_{mod} \rightarrow X$.) More generally, for a point $x \in X$ and a closed subset $A \subset \partial_\infty X$, we define the *Weyl cone* $V(x, A)$ as the union of all rays $x\xi$ for $\xi \in A$. It is, in general, not flat.

The stabilizers $B_\sigma \subset G$ of the chambers $\sigma \subset \partial_\infty X$ are the *Borel subgroups* of G . After identifying the model chamber with a chamber in $\partial_\infty X$, $\sigma_{mod} \subset \partial_\infty X$, we call $B = B_{\sigma_{mod}}$ the *positive* Borel subgroup. The group G acts transitively on the set of chambers in $\partial_\infty X$, which we will then identify with G/B , the *full flag manifold* of G . The Borel subgroups are algebraic subgroups of G , and G/B is a real projective variety. The set $\partial_F X \cong G/B$ of chambers in $\partial_\infty X$ is called the *Fürstenberg boundary* of X ; we will equip it with the visual topology (as opposed to the Zariski topology coming from G/B) which coincides with its manifold topology as a compact homogeneous G -space. After picking an interior point $\xi \in \text{int}(\sigma_{mod})$, we can identify the G -orbit $G\xi \subset \partial_\infty X$ G -equivariantly and homeomorphically with $\partial_F X$ by assigning to the (regular) point $g\xi$ the (unique) chamber $g\sigma_{mod}$ containing it.

The stabilizers $P_\tau \subset G$ of simplices $\tau \subset \partial_\infty X$ are the *parabolic subgroups* of G . The group G acts transitively on simplices of the same type. The set $\text{Flag}(\tau_{mod}) \cong G/P_{\tau_{mod}}$ of the simplices τ of type $\theta(\tau) = \tau_{mod} \subset \sigma_{mod}$ is called the *partial flag manifold*. In particular, $\text{Flag}(\sigma_{mod}) = \partial_F X$. Again, we equip the flag manifolds with the visual topology; it agrees with their topology as compact homogeneous G -spaces.

We also fix a Riemannian metric on each flag manifold $\text{Flag}(\tau_{mod})$; the particular choice of the metric will be irrelevant.

For a flag manifold $\text{Flag}(\tau_{mod})$ and a simplex $\hat{\tau}$ of type $\iota(\tau_{mod})$ we define the *open Schubert stratum* $C(\hat{\tau}) \subset \text{Flag}(\tau_{mod})$ as the subset of simplices opposite to $\hat{\tau}$. It follows from semicontinuity of the Tits distance that the subset $C(\hat{\tau}) \subset \text{Flag}(\tau_{mod})$ is indeed open. Furthermore, this subset is also dense in $\text{Flag}(\tau_{mod})$. We note that for rank 1 symmetric spaces, the only flag manifold associated to G is $\partial_\infty X$ and the open Schubert strata are the complements of points.

2.4 Parallel sets, cones, horocycles and decompositions of symmetric spaces

2.4.1 Parallel sets

Let $s \subset \partial_{Tits} X$ be an isometrically embedded unit sphere. We denote by $P(s) \subset X$ the *parallel set* associated to s . It can be defined as the union of maximal flats $F \subset X$ asymptotic to s , $s \subset \partial_\infty F$. Alternatively, one can define it as the union of flats $f \subset X$ with ideal boundary $\partial_\infty f = s$. The parallel set is a totally geodesic subspace and splits metrically as the product

$$P(s) \cong f \times CS(s) \tag{2.5}$$

of any of these flats and a symmetric space $CS(s)$ called its *cross section*. Accordingly, the ideal boundary of the parallel set is a metric suspension

$$\partial_{Tits} P(s) \cong \partial_{Tits} f \circ \partial_{Tits} CS(s). \tag{2.6}$$

It coincides with the subbuilding $B(s) \subset \partial_\infty X$ consisting of the union of all apartments $a \subset \partial_\infty X$ containing s ,

$$B(s) = \partial_\infty P(s).$$

It is immediate that parallel sets are nonpositively curved symmetric spaces. However, they do not have noncompact type as their Euclidean de Rham factors are nontrivial. The factor f in the splitting (2.6) of the parallel set is then the Euclidean de Rham factor and the cross section $CS(s)$ has trivial euclidean de Rham factor, i.e. it is a symmetric space of noncompact type.

For a pair of antipodal simplices $\tau_+, \tau_- \subset \partial_\infty X$ there exists a unique minimal singular sphere $s(\tau_-, \tau_+) \subset \partial_\infty X$ containing them. We denote $P(\tau_-, \tau_+) := P(s(\tau_-, \tau_+))$; this parallel set is the union of (maximal) flats $F \subset X$ whose ideal boundaries contain $\tau_- \cup \tau_+$. In order to simplify the notation, we will denote $B(s(\tau_-, \tau_+))$ simply by $B(\tau_-, \tau_+)$.

2.4.2 Stars, Weyl cones and diamonds

Definition 2.7 (Stars). Let $\tau \subset \partial_{Tits} X$ be a simplex. We define the *star* $st(\tau)$ of the open simplex $\text{int}(\tau)$ as the subcomplex of $\partial_{Tits} X$ consisting of all simplices intersecting the open simplex $\text{int}(\tau)$ nontrivially (i.e., containing τ). In other words, $st(\tau)$ is the smallest subcomplex of $\partial_{Tits} X$ containing all chambers σ such that $\tau \subset \sigma$. We note that $st(\tau)$ is also known as the *residue* of τ , see e.g. [AB].

We define the *open star* $ost(\tau) \subset \partial_\infty X$ as the union of all open simplices whose closure intersects $\text{int}(\tau)$ nontrivially. For the model simplex τ_{mod} , we will use the notation $ost(\tau_{mod})$ to denote its open star in the simplicial complex consisting of faces of σ_{mod} .

Note that $ost(\tau)$ is an open subset of the simplex σ_{mod} ; it does not include any open faces of τ except for the interior of τ . Furthermore, $\partial st(\tau) = st(\tau) - ost(\tau)$ is the union of all panels π of type $\theta(\pi) \not\supset \tau_{mod}$ which are contained in a chamber with face τ .

τ_{mod} -regularity. Using the notion of open stars we now generalize the standard notion of regularity in $\partial_{Tits} X$ to *regularity relative to faces τ_{mod} of σ_{mod}* . Let τ_{mod} be a face of σ_{mod} . A point $\xi \in \partial_{Tits} X$ such that $\theta(\xi) \in ost(\tau_{mod})$, is called τ_{mod} -regular. If $\Theta \subset ost(\tau_{mod})$ is a compact subset, then we will refer to points $\xi \in \partial_{Tits} X$ such that $\theta(\xi) \in \Theta$, as being Θ -regular. Analogously to the definition of regular geodesic segments, a nondegenerate geodesic segment xy is called τ_{mod} -regular, resp. Θ -regular if it is contained in a geodesic ray $x\xi$ with ξ τ_{mod} -regular, resp. Θ -regular.

We note that each subset Θ as above determines the simplex τ_{mod} , namely, τ_{mod} is the smallest face of σ_{mod} such that $\Theta \subset ost(\tau_{mod})$.

The fact that the diameter of σ_{mod} is $\leq \frac{\pi}{2}$ immediately implies:

Lemma 2.8. *For every interior point $\xi \in \tau_{mod}$ and every compact subset $\Theta \subset ost(\tau_{mod})$ we have*

$$\Theta \subset B(\xi, \frac{\pi}{2}).$$

An isolation property in subbuildings $B(s)$.

Lemma 2.9. *Let $s \subset \partial_\infty X$ be a singular sphere. Then the following hold:*

(i) *The simplices contained in s are isolated among the simplices contained in $B(s) = \partial_\infty P(s)$. In other words: If $\tau_n \rightarrow \tau$ is a converging sequence of simplices $\tau_n \subset B(s)$ with limit simplex $\tau \subset s$, then $\tau_n = \tau$ for large n .*

(ii) *For a simplex $\tau \subset s$, the subset $\text{ost}(\tau) \cap B(s)$ is open in $B(s)$ with respect to the visual topology. In particular, if τ is top-dimensional in s , then $\text{ost}(\tau)$ is an open subset of $B(s)$.*

Proof. In view of the decomposition (2.6) of $B(s)$ as a metric suspension, a point $\xi \in s$ has a unique antipode $\hat{\xi}$ in $B(s)$, and this antipode is contained in s , $\hat{\xi} \in s$. Furthermore,

$$\angle_{\text{Tits}}(\xi, \cdot) + \angle_{\text{Tits}}(\cdot, \hat{\xi}) \equiv \pi \quad (2.10)$$

on $B(s)$. We recall that, due to the lower semicontinuity of the Tits metric, Tits closed balls $\bar{B}(\eta, r)$ in $\partial_\infty X$ are closed also with respect to the visual topology. Therefore (2.10) implies that Tits open balls $B(\xi, r) \cap B(s)$ in $B(s)$ centered at $\xi \in s$ are open in $B(s)$ also with respect to the visual topology, because $B(\xi, r) \cap B(s) = B(s) - \bar{B}(\hat{\xi}, \pi - r)$.

We recall furthermore that, due to the finiteness of possible Tits distances between points of a fixed type $\bar{\xi} \in \sigma_{\text{mod}}$, the subset $\theta^{-1}\theta(\xi)$ is Tits discrete, i.e. $B(\xi, \epsilon) \cap \theta^{-1}\theta(\xi) = \{\xi\}$ for sufficiently small $\epsilon > 0$, depending on $\theta(\xi)$. It follows that ξ is an *isolated* point of $\theta^{-1}\theta(\xi) \cap B(s)$ with respect to the visual topology, i.e. it is isolated among points in $B(s)$ of the same type.

Now we prove (i). Since the face type of the τ_n must stabilize, we may assume that it is constant, i.e. $\theta(\tau_n) = \tau_{\text{mod}} \subset \sigma_{\text{mod}}$ for all n and $\theta(\tau) = \tau_{\text{mod}}$. We choose a type $\bar{\xi} \in \text{int}(\tau_{\text{mod}})$ and consider the points $\xi_n \in \text{int}(\tau_n)$ and $\xi \in \text{int}(\tau)$ of type $\theta(\xi_n) = \theta(\xi) = \bar{\xi}$. Then $\xi_n \rightarrow \xi$. Since ξ is isolated in $\theta^{-1}\theta(\xi) \cap B(s)$, it follows that $\xi_n = \xi$ and hence $\tau_n = \tau$ for large n .

To verify (ii), we note that the subset $\text{st}(\tau) \cap B(s)$ is the union of all chambers σ with $\tau \subset \sigma \subset B(s)$. This family of chambers is obviously closed and thus compact in the space of all chambers contained in $B(s)$. It is also *open* in it as a consequence of part (i). Indeed, if $\sigma_n \rightarrow \sigma$ is a converging sequence of chambers $\sigma_n \subset B(s)$, then $\tau_n \rightarrow \tau$ for the faces $\tau_n \subset \sigma_n$ of type $\theta(\tau_n) = \theta(\tau)$, and it follows that $\tau_n = \tau$ and hence $\tau \subset \sigma_n$ for large n .

Consider now a sequence of points $\eta_n \in B(s)$ such that $\eta_n \rightarrow \eta \in \text{ost}(\tau)$. We must show that $\eta_n \in \text{ost}(\tau)$ for large n . Let $\sigma_n \subset B(s)$ be chambers containing them, $\eta_n \in \sigma_n$. It suffices to check that $\sigma_n \subset \text{st}(\tau)$ for large n , because $\theta(\eta_n) \rightarrow \theta(\eta)$, and hence $\theta(\eta_n) \in \text{ost}(\theta(\tau)) \subset \sigma_{\text{mod}}$ for large n . Suppose the contrary, i.e. that one can pass to a subsequence such that $\sigma_n \not\subset \text{st}(\tau)$ for all n . We may assume that $\sigma_n \rightarrow \sigma \subset B(s)$. By the openness above, it follows that $\sigma \not\subset \text{st}(\tau)$, equivalently $\tau \not\subset \sigma$. On the other hand, $\eta \in \sigma$. Together with $\eta \in \text{ost}(\tau)$ this implies that $\tau \subset \sigma$, a contradiction. \square

Convexity of stars.

Lemma 2.11. *The star $\text{st}(\bar{\tau})$ of a simplex $\bar{\tau} \subset a_{\text{mod}}$ is a convex subset of a_{mod} . Furthermore, $\text{st}(\bar{\tau})$ equals the intersection of the simplicial hemispheres $\bar{h} \subset a_{\text{mod}}$ such that $\text{int}(\bar{\tau}) \subset \text{int} \bar{h}$.*

Proof. If a hemisphere \bar{h} contains a simplex $\bar{\tau}$, but does not contain it in its boundary, then all chambers containing this simplex as a face belong to the (closed) hemisphere. Vice versa, if a chamber $\bar{\sigma}$ does not contain $\bar{\tau}$ as a face, then there exists a wall which separates $\bar{\sigma}$ from $\bar{\tau}$. \square

Similarly, the star $\text{st}(\tau)$ of a simplex $\tau \subset \partial_{Tits}X$ is a convex subset of $\partial_{Tits}X$. One can represent it as the intersection of all simplicial $\frac{\pi}{2}$ -balls which contain $\text{int}(\tau)$ in their interior. One can represent $\text{st}(\tau)$ also as the intersection of fewer balls:

Lemma 2.12 (Convexity of stars). (i) *Let $\tau \subset \partial_{Tits}X$ be a simplex. Then $\text{st}(\tau)$ equals the intersection of the simplicial $\frac{\pi}{2}$ -balls whose interior contains $\text{int}(\tau)$.*

(ii) *For any simplex $\hat{\tau}$ opposite to τ , the star $\text{st}(\tau)$ equals the intersection of the subbuilding $B(\tau, \hat{\tau}) = \partial_{\infty}P(\tau, \hat{\tau})$ with all simplicial $\frac{\pi}{2}$ -balls whose interior contains $\text{int}(\tau)$ and whose center lies in this subbuilding.*

Proof. (i) If a simplicial $\frac{\pi}{2}$ -ball contains a simplex τ , but does not contain it in its boundary, then all chambers containing this simplex as a face belong to this ball. Vice versa, let σ be a chamber which does not contain τ as a face. There exists an apartment $a \subset \partial_{Tits}X$ which contains σ and τ . As before in the proof of Lemma 2.11, there exists a simplicial hemisphere $h \subset a$ containing τ but not σ . Then the simplicial $\frac{\pi}{2}$ -ball with the same center as h contains τ but not σ .

(ii) Note first that $\text{st}(\tau) \subset B(\tau, \hat{\tau})$. Then we argue as in part (i), observing that if $\sigma \subset B(\tau, \hat{\tau})$ then a can be chosen inside $B(\tau, \hat{\tau})$. \square

Convexity of cones.

Now we prove a corresponding convexity statement in the symmetric space, namely that the Weyl cones $V(x, \text{st}(\tau))$ are convex. We begin with

Lemma 2.13. *For every $x \in P(\tau, \hat{\tau})$, the Weyl cone $V(x, \text{st}(\tau))$ is contained in the parallel set $P(\tau, \hat{\tau})$.*

Proof. Consider a chamber σ in $\partial_{Tits}X$ containing τ . The Weyl sector $V(x, \sigma)$ is contained in a (unique maximal) flat $F \subset X$. Since $\tau, \hat{\tau}$ are antipodal with respect to x , $\tau \cup \hat{\tau} \subset \partial_{\infty}F$. Therefore, $F \subset P(\tau, \hat{\tau})$. \square

Proposition 2.14 (Convexity of Weyl cones). *Let $\hat{\tau}$ be the simplex opposite to τ with respect to x . Then the Weyl cone $V(x, \text{st}(\tau))$ is the intersection of the parallel set $P(\tau, \hat{\tau})$ with the horoballs which are centered at $\partial_{\infty}P(\tau, \hat{\tau})$ and contain $V(x, \text{st}(\tau))$.*

Proof. One inclusion is clear. We must prove that each point $y \in P(\tau, \hat{\tau}) \setminus V(x, \text{st}(\tau))$ is not contained in one of these horoballs. There exists a maximal flat $F \subset P(\tau, \hat{\tau})$ containing x and y . (Any two points in a parallel set lie in a common maximal flat.) We extend the oriented segment xy to a ray $x\eta$ inside F .

As in the proof of Lemma 2.12, there exists $\zeta \in \partial_{\infty}F$ such that $\bar{B}(\zeta, \frac{\pi}{2})$ contains $\text{st}(\tau)$ but does not contain η . Then the horoball $Hb_{\zeta, x}$ intersects F in a half-space which contains x in its

boundary hyperplane but does not contain η in its ideal boundary. Therefore does not contain y . By convexity, $V(x, \text{st}(\tau)) \subset Hb_{\zeta, x}$. \square

We will need a version of the above convexity results for more general stars and cones.

Definition 2.15 (Weyl convex). A subset $\Theta \subseteq \sigma_{mod}$ is called τ_{mod} -Weyl convex, if its symmetrization $W_{\tau_{mod}}\Theta \subseteq \text{st}(\sigma_{mod})$ is a convex subset of a_{mod} .

Below, Θ will always denote a τ_{mod} -Weyl convex subset of σ_{mod} .

Weyl convexity implies convexity.

Note that σ_{mod} itself is Weyl convex, since $W_{\tau_{mod}}\sigma_{mod} = \text{st}(\tau_{mod})$ is convex. A point $\bar{\xi} \in \sigma_{mod}$ is a Weyl convex subset if and only if it belongs to τ_{mod} .

Definition 2.16 (Θ -stars). We define the Θ -star of a simplex $\tau \subset \partial_{\infty}X$ of type τ_{mod} as $\text{st}_{\Theta}(\tau) = \text{st}(\tau) \cap \theta^{-1}(\Theta)$.

The symmetrization $W_{\tau_{mod}}\Theta \subset a_{mod}$ equals the Θ -star of τ_{mod} inside the model apartment, $\text{st}_{\Theta}^{a_{mod}}(\tau_{mod}) = W_{\tau_{mod}}\Theta$.

Our next result establishes convexity of Θ -stars. More precisely:

Lemma 2.17 (Convexity of Θ -stars). *For every simplex $\tau \subset \partial_{\infty}X$ of type τ_{mod} , the Θ -star $\text{st}_{\Theta}(\tau) \subset \partial_{\infty}X$ equals the intersection of all $\frac{\pi}{2}$ -balls containing it.*

Proof. Let $\zeta \in \partial_{\infty}X$. For an apartment $a \subset \partial_{\infty}X$ containing τ and ζ , we have $a \cap \text{st}_{\Theta}(\tau) = \text{st}_{\Theta}^a(\tau)$, the intrinsic star of τ inside the apartment a (viewed as a thin building). Moreover, $\text{st}_{\Theta}(\tau)$ equals the union of all these intersections with apartments.

By definition of spherical buildings, for any two apartments $a, a' \subset \partial_{\infty}X$ containing τ and ζ , there exists an isometry $a \rightarrow a'$ fixing (the convex hull of) τ and ζ . This identification carries $\text{st}_{\Theta}(\tau) \cap a$ to $\text{st}_{\Theta}(\tau) \cap a'$. Hence $\text{st}_{\Theta}(\tau) \subset B(\zeta, \frac{\pi}{2})$ if and only if $\text{st}_{\Theta}(\tau) \cap a \subset B(\zeta, \frac{\pi}{2})$ for one (any) of these apartments a . This shows that the intersection of all $\frac{\pi}{2}$ -balls containing $\text{st}(\tau)$ is not strictly bigger than $\text{st}(\tau)$, since any point in $\partial_{\infty}X$ lies in a common apartment with τ . \square

Proposition 2.18 (Convexity of Θ -cones). *For every point $x \in X$ and every simplex $\tau \subset \partial_{\infty}X$ of type τ_{mod} the Θ -cone $V(x, \text{st}_{\Theta}(\tau))$ is convex of X .*

Proof. In view of Lemma 2.17, the proof of Proposition 2.14 goes through. \square

The following consequence will be important for us.

Corollary 2.19 (Nested Θ -cones). *If $x' \in V(x, \text{st}_{\Theta}(\tau))$, then $V(x', \text{st}_{\Theta}(\tau)) \subset V(x, \text{st}_{\Theta}(\tau))$.*

Let $xy \subset X$ be an oriented τ_{mod} -regular geodesic segment. Then we define the simplex $\tau = \tau(xy) \subset \partial_{\infty}X$ as follows: Forward extend the segment xy to the geodesic ray $x\xi$, and let τ be the unique face of type τ_{mod} of $\partial_{Tits}X$ such that $\xi \in \text{st}(\tau)$.

Definition 2.20 (Diamond). We define the Θ -diamond of a Θ -regular segment x_-x_+ as

$$\diamond_{\Theta}(x_-, x_+) = V(x_-, \text{st}_{\Theta}(\tau_+)) \cap V(x_+, \text{st}_{\Theta}(\tau_-)) \subset P(\tau_-, \tau_+)$$

where $\tau_{\pm} = \tau(x_{\mp}x_{\pm})$.

The next result follows immediately from Corollary 2.19.

Lemma 2.21. *If $x'_-x'_+$ is a Θ -regular segment contained in $\diamond_{\Theta}(x'_-, x'_+)$ and if $\tau(x'_{\mp}x'_{\pm}) = \tau(x_{\mp}x_{\pm})$, then $\diamond_{\Theta}(x'_-, x'_+) \subset \diamond_{\Theta}(x_-, x_+)$.*

2.4.3 Strong asymptote classes

Recall that two unit speed geodesic rays $\rho_1, \rho_2 : [0, +\infty) \rightarrow X$ in a Hadamard manifold are called *asymptotic* if the convex function $t \mapsto d(\rho_1(t), \rho_2(t))$ on $[0, +\infty)$ is bounded, and they are called *strongly asymptotic* if $d(\rho_1(t), \rho_2(t)) \rightarrow 0$ as $t \rightarrow +\infty$. In the case when X is a symmetric space, one verifies using Jacobi fields on X that the decay is exponential with rate depending on the type of the ideal boundary point $\rho_1(+\infty) = \rho_2(+\infty)$ (see [Eb]).

We generalize these two notions to sectors. A sector $V(x, \tau)$ has a canonical isometric parametrization by a *sector chart* $\kappa_{V(x, \tau)} : V(0, \theta(\tau)) \rightarrow V(x, \tau)$ preserving types at infinity; here, $\theta(\tau) \subset \sigma_{mod}$ is the type of the simplex τ and $V(0, \theta(\tau))$ is a face of the model sector V_{mod} .

For two sectors $V(x_1, \tau_1)$ and $V(x_2, \tau_2)$ of the same type, $\theta(\tau_1) = \theta(\tau_2)$, the distance function from points in $\kappa_{V(x_1, \tau_1)}$ to the sector $\kappa_{V(x_2, \tau_2)}$

$$d(\kappa_{V(x_1, \tau_1)}, \kappa_{V(x_2, \tau_2)}) : V(0, \theta(\tau_1)) \rightarrow [0, +\infty) \quad (2.22)$$

is convex. The two sectors are called *asymptotic*, if this distance function is bounded, equivalently, if they coincide at infinity, $\tau_1 = \tau_2$. For two asymptotic sectors $V(x_1, \tau)$ and $V(x_2, \tau)$, we define

$$d_{\tau}(x_1, x_2) := \inf d(\kappa_{V(x_1, \tau)}, \kappa_{V(x_2, \tau)});$$

this defines a pseudo-metric d_{τ} on X , viewed as the set of (tips of) sectors asymptotic to τ .

Definition 2.23. The sectors $V(x_1, \tau)$ and $V(x_2, \tau)$ are *strongly asymptotic* if $d_{\tau}(x_1, x_2) = 0$.

This is equivalent to the property that for some (any) $\xi \in \text{int}(\tau)$ the rays $x_1\xi$ and $x_2\xi$ are strongly asymptotic.

We denote by

$$X_{\tau}^{par} = X / \sim_{d_{\tau}}$$

the *space of (parametrized) strong asymptote classes* of sectors asymptotic to τ .

We show next that parallel sets represent strong asymptote classes. For a simplex $\hat{\tau}$ opposite to τ we consider the restriction

$$P(\tau, \hat{\tau}) \rightarrow X_{\tau}^{par} \quad (2.24)$$

of the projection $X \rightarrow X_{\tau}^{par}$. We observe that for points $x_1, x_2 \in P(\tau, \hat{\tau})$ the distance function (2.22) is constant $\equiv d(x_1, x_2)$. Hence (2.24) is an isometric embedding. To see that it is

also surjective, we need to verify that every sector $V(x, \tau)$ is strongly asymptotic to a sector $V(x', \tau) \subset P(\tau, \hat{\tau})$. This follows from the corresponding fact for geodesics:

Lemma 2.25. *Let $\xi, \hat{\xi}$ be antipodal ideal points. Then every geodesic asymptotic to ξ is strongly asymptotic to a geodesic whose other end is asymptotic to $\hat{\xi}$.*

Proof. Let $c_1(t)$ be a unit speed geodesic forward asymptotic to ξ . Then $t \mapsto d(c_1(t), P(\xi, \hat{\xi}))$ is convex and bounded on $[0, +\infty)$, and hence non-increasing. We claim that the limit

$$d := \lim_{t \rightarrow \infty} d(c_1(t), P(\xi, \hat{\xi}))$$

equals zero. To see this, we choose a unit speed geodesic $c_2(t)$ in $P(\xi, \hat{\xi})$ forward asymptotic to ξ and use the transvections along it to “pull back” c_1 : The geodesics $c_1^s := T_{-s}^{c_2} c_1(\cdot + s)$ form a bounded family as $s \rightarrow +\infty$ and subconverge to a geodesic $c_1^{+\infty}$. Since the transvections $T_s^{c_2}$ preserve the parallel set $P(\xi, \hat{\xi})$, the distance functions $d(c_1^s(\cdot), P(\xi, \hat{\xi})) = d(c_1(\cdot + s), P(\xi, \hat{\xi}))$ converge locally uniformly on \mathbb{R} and uniformly on $[0, +\infty)$ to the constant d . It follows that the limit geodesic $c_1^{+\infty}$ has distance $\equiv d$ from $P(\xi, \hat{\xi})$. The same argument, applied to c_2 instead of the parallel set, implies that $c_1^{+\infty}$ is parallel to c_2 . Thus, $d = 0$.

Now we find a geodesic in $P(\xi, \hat{\xi})$ strongly asymptotic to c_1 as follows. Let $t_n \rightarrow +\infty$. Then there exist unit speed geodesics $c'_n(t)$ in $P(\xi, \hat{\xi})$ forward asymptotic to ξ and with $d(c'_n(t_n), c_1(t_n)) = d(c_1(t_n), P(\xi, \hat{\xi})) \rightarrow 0$. This family of parallel geodesics c'_n is a Cauchy family and converges to a geodesic in $P(\xi, \hat{\xi})$ which is strongly asymptotic to c_1 . \square

We conclude:

Corollary 2.26. *The map (2.24) is an isometry.*

Let $\xi \in \partial_\infty X$, and let $c(t)$ be a geodesic asymptotic to it, $c(+\infty) = \xi$. We observe that for every $\eta \in \partial_\infty P(c)$ the restriction $b_\eta \circ c$ is linear, because there exists a flat f containing c and asymptotic to η , $\eta \in \partial_\infty f$.

As a consequence, for any two strongly asymptotic geodesics $c_1(t)$ and $c_2(t)$ at η , the restricted Busemann functions $b_\eta \circ c_i$ coincide for every $\eta \in \text{st}(\xi) \subset \partial_\infty P(c_1) \cap \partial_\infty P(c_2)$. In fact, there is the following criterion for strong asymptoticity:

Lemma 2.27. *For geodesics $c_1(t)$ and $c_2(t)$ asymptotic to $\xi \in \partial_\infty X$ the following are equivalent:*

- (i) $c_1(t)$ and $c_2(t)$ are strongly asymptotic.
- (ii) $b_\eta \circ c_1 = b_\eta \circ c_2$ for every $\eta \in \text{st}(\xi)$.
- (ii') $b_\eta \circ c_1 = b_\eta \circ c_2$ for every $\eta \in B(\xi, \epsilon)$ for some $\epsilon > 0$.

Proof. We may replace the geodesics c_i by parallel ones without changing their strong asymptote classes (Lemma 2.25) and hence assume that they lie in one flat. Then the assertion is clear. \square

2.4.4 Horocycles and horocyclic subgroups

We fix a simplex $\tau \subset \partial_\infty X$, respectively, a parabolic subgroup $P_\tau \subset G$ and discuss various foliations of X naturally associated to it.

We begin with foliations by flats and parallel sets: First, we denote by \mathcal{F}_τ the partition of X into minimal flats asymptotic to τ , i.e. singular flats $f \subset X$ such that τ is a top-dimensional simplex in $\partial_\infty f$. Second, any simplex $\hat{\tau}$ opposite to τ spans together with τ a singular sphere $s(\tau, \hat{\tau}) \subset \partial_\infty X$ and determines the parallel set $P(\tau, \hat{\tau}) := P(s(\tau, \hat{\tau}))$ with cross section $CS(\tau, \hat{\tau}) := CS(s(\tau, \hat{\tau}))$. The parallel sets $P(\tau, \hat{\tau})$ for all $\hat{\tau}$ form a partition \mathcal{P}_τ of X , which is a coarsening of \mathcal{F}_τ . The parabolic subgroup P_τ preserves both partitions and acts transitively on their leaves, because it acts transitively on X . (This in turn can be derived e.g. from the transitivity of G on maximal flats.) This implies that these partitions are smooth foliations.

We describe now preferred identifications of the leaves of these foliations by the actions of certain subgroups of P_τ . Their orbits will be the submanifolds orthogonal and complementary to the foliations, i.e. the integral submanifolds of the distributions normal to the foliations.

The tuple $(b_\xi)_{\xi \in \text{Vert}(\tau)}$ of Busemann functions for the vertices ξ of τ (well-defined up to additive constants) provides affine coordinates simultaneously for each of the flats in \mathcal{F}_τ . The Busemann functions at the other ideal points in τ are linear combinations of these. The normal subgroup

$$\bigcap_{\xi \in \text{Vert}(\tau)} \text{Stab}(b_\xi) = \bigcap_{\xi \in \tau} \text{Stab}(b_\xi) \subset P_\tau \quad (2.28)$$

acts transitively on the set of these flats and preserves the coordinates; it thus provides consistent preferred identifications between them. The level sets of $(b_\xi)_{\xi \in \text{Vert}(\tau)}$ are submanifolds orthogonal to the flats in \mathcal{F}_τ , because the gradient directions of the Busemann functions b_ξ at a point $x \in f \in \mathcal{F}_\tau$ span the tangent space $T_x f$. They form a smooth foliation \mathcal{F}_τ^\perp and are the orbits of the group (2.28).

We define the *horocyclic subgroup* at τ as the *normal subgroup*

$$N_\tau = \bigcap_{\xi \in \text{ost}(\tau)} \text{Stab}(b_\xi) \subset \text{Fix}(\text{st}(\tau)) \triangleleft P_\tau. \quad (2.29)$$

Note that as a consequence of Lemma 2.27, N_τ preserves the strong asymptote classes of geodesics at all ideal points $\xi \in \text{ost}(\tau)$.

We now give a method for constructing isometries in N_τ .

Let $\xi \in \partial_\infty X$ be an ideal point, and let $c(t)$ be a unit speed geodesic forward asymptotic to it, $c(+\infty) = \xi$. Consider the one parameter group (T_t^c) of transvections along c . The T_t^c fix $\partial_\infty P(c)$ pointwise and shift the Busemann functions b_η for $\eta \in \partial_\infty P(c)$ by additive constants:

$$b_\eta \circ T_t^c - b_\eta \equiv -t \cdot \cos \angle_{Tits}(\eta, \xi)$$

Lemma 2.30. *Let $c_1(t)$ and $c_2(t)$ be geodesics forward asymptotic to ξ , which are strongly asymptotic. Then there exists an isometry $n \in G$ with the properties:*

- (i) $n \circ c_1 = c_2$.
- (ii) n fixes $\partial_\infty P(c_1) \cap \partial_\infty P(c_2)$ pointwise.
- (iii) $b_\eta \circ n \equiv b_\eta$ for all $\eta \in \partial_\infty P(c_1) \cap \partial_\infty P(c_2)$.

In particular, $n \in N_\tau$ for the simplex τ spanned by ξ , $\xi \in \text{int}(\tau)$.

Proof. By our observation above, the isometries $T_{-t}^{c_2} \circ T_t^{c_1}$ fix $\partial_\infty P(c_1) \cap \partial_\infty P(c_2)$ pointwise and preserve the Busemann functions b_η for all $\eta \in \partial_\infty P(c_1) \cap \partial_\infty P(c_2)$. (The geodesics c_i need not have unit speed; they have the same positive speed since they are strongly asymptotic.) Moreover, they form a bounded family and, as $t \rightarrow +\infty$, subconverge to an isometry $n \in G$ with the same properties and which maps c_1 to c_2 while preserving parametrizations, compare the proof of Lemma 2.25. The last assertion follows because $\text{st}(\tau) \subset \partial_\infty P(c_1) \cap \partial_\infty P(c_2)$. \square

Corollary 2.31. N_τ acts transitively on

- (i) every strong asymptote class of geodesics at every ideal point $\xi \in \text{int}(\tau)$;
- (ii) the set of leaves of \mathcal{P}_τ .

Proof. Part (i) is a direct consequence.

To verify (ii), we choose $\xi \in \text{int}(\tau)$. Given leaves $P(\tau, \hat{\tau}_i)$ of \mathcal{P}_τ , we let $c_i(t)$ be unit speed geodesics in $P(\tau, \hat{\tau}_i)$ forward asymptotic to ξ . They may be chosen strongly asymptotic by Lemma 2.25. The parallel set of c_i equals $P(\tau, \hat{\tau}_i)$ because ξ is an interior point of τ . Hence an isometry in N_τ carrying c_1 to c_2 carries $P(\tau, \hat{\tau}_1)$ to $P(\tau, \hat{\tau}_2)$. \square

Remark 2.32. One also obtains that every geodesic asymptotic to an ideal point $\xi \in \partial\tau$ can be carried by an isometry in N_τ to any other strongly asymptotic geodesic. However, N_τ does not preserve strong asymptote classes at ξ in that case.

Lemma 2.33. If $n \in N_\tau$ preserves a leaf $P(\tau, \hat{\tau})$, $n\hat{\tau} = \hat{\tau}$, then it acts trivially on it.

Proof. Then n fixes $\text{st}(\tau)$ and $\hat{\tau}$ pointwise, and hence their Tits convex hull $\partial_\infty P(\tau, \hat{\tau})$. Thus n preserves every maximal flat F in $P(\tau, \hat{\tau})$. Moreover it preserves the Busemann functions b_ξ at all $\xi \in \partial_\infty F \cap \text{st}(\tau)$, and hence must fix F pointwise, compare Lemma 2.27. \square

Thus, N_τ provides consistent preferred identifications between the parallel sets $P(\tau, \hat{\tau})$. The N_τ -orbits are submanifolds orthogonal to the parallel sets. They form a smooth foliation

$$\mathcal{H}_\tau = \mathcal{P}_\tau^\perp \tag{2.34}$$

refining \mathcal{F}_τ^\perp , which we call the *horocyclic foliation* and its leaves the *horocycles* at τ . We denote the horocycle at τ through the point x by Hc_x^τ , i.e. $Hc_x^\tau = N_\tau x$.

For incident faces $v \subset \tau$, the associated subgroups and foliations are contained in each other. For instance, we have $\text{st}(v) \supset \text{st}(\tau)$ and $N_v \subset N_\tau$.

We next relate horocycles and strong asymptote classes.

Proposition 2.35 (Strong asymptote classes are horocycles). *The sectors $V(x_1, \tau)$ and $V(x_2, \tau)$ are strongly asymptotic if and only if x_1 and x_2 lie in the same horocycle at τ .*

Proof. Let $\xi \in \text{int}(\tau)$. By Corollary 2.31(ii), N_τ acts transitively on every strong asymptote class of geodesics at ξ , and hence of sectors at τ . Thus, strong asymptote classes are contained in horocycles.

On the other hand, they cannot be strictly larger because every strong asymptote class intersects every parallel set, cf. the surjectivity of (2.24), and every horocycle intersects every parallel set exactly once. \square

Our discussion shows that there is the exact sequence

$$N_\tau \rightarrow P_\tau \rightarrow \text{Isom}(X_\tau^{\text{par}}).$$

Remark 2.36. Note that the homomorphism $P_\tau \rightarrow \text{Isom}(X_\tau^{\text{par}})$ is (in general) not surjective. Namely, let $f \times CS(s)$ denote the de Rham decomposition with the maximal flat factor f . Then the image of the above homomorphism (if $\dim(f) > 1$) does not contain the full group of rotations of f . This can be corrected as follows. Let A_τ denote the group of translations of f , and let M_τ be the isometry group of $CS(s)$. Then the above exact sequence is a part of the *Langlands' decomposition* of the group P_τ ,

$$1 \rightarrow N_\tau \rightarrow P_\tau \rightarrow A_\tau \times M_\tau \rightarrow 1,$$

which, on the level of Lie algebras, is a split exact sequence.

We return now to Lemma 2.30. For later use, we elaborate on the special case when the geodesics c_i are contained in the parallel set of a singular flat of dimension rank minus one.

For an half-apartment $h \subset \partial_\infty X$, we define its *star* $\text{st}(h)$ as the union of the stars $\text{st}(\tau)$ where τ runs through all simplices with $\text{int}(\tau) \subset \text{int}(h)$, equivalently, which are spanned by an interior point of h . Similarly, we define the *open star* $\text{ost}(h)$ as the union of the corresponding open stars $\text{ost}(\tau)$. Note that $\text{int}(h) \subset \text{ost}(h)$. Furthermore, we define the closed subgroup $N_h \subset G$ as the intersection of the horocyclic subgroups N_τ at these simplices τ .

We observe that N_h preserves the strong asymptote classes of geodesics at all ideal points $\xi \in \text{ost}(h)$, and it permutes the maximal flats F asymptotic to h , $\partial_\infty F \supset h$. The next result shows that it acts transitively on them:

Lemma 2.37. *Let $h \subset \partial_\infty X$ be a half-apartment, and let $F_1, F_2 \subset P(\partial h)$ be maximal flats asymptotic to h , $\partial_\infty F_i \supset h$. Then there exists an isometry $n \in N_h$ with the properties:*

- (i) $nF_1 = F_2$.
- (ii) n fixes $\text{st}(h)$ pointwise.
- (iii) $b_\eta \circ n \equiv b_\eta$ for all $\eta \in \text{st}(h)$.

Proof. In the metric decomposition $P(\partial h) \cong \mathbb{R}^{\text{rank}(X)-1} \times CS(\partial h)$ (see (2.5)), the maximal flats F_i correspond to a pair of asymptotic, and hence strongly asymptotic geodesics \bar{c}_i in the rank one symmetric space $CS(\partial h)$.

Let $\xi, \xi' \in \text{int}(h)$. Let $c_1(t)$ and $c_2(t)$ be strongly asymptotic geodesics at ξ so that $c_i \subset F_i$. Then they project (up to reparameterization) to the strongly asymptotic geodesics \bar{c}_i in $CS(\partial h)$, and their projections to the Euclidean de Rham factor of $P(\partial h)$ coincide. Analogously, let $c'_i \subset F_i$ be strongly asymptotic geodesics at ξ' . Their parametrizations can be chosen so that their projections to $CS(\partial h)$ coincide with the projections of the c_i . Then

$$T_{-t}^{c_2} \circ T_t^{c_1} = T_{-t}^{c'_2} \circ T_t^{c'_1}$$

and the isometry n produced in the proof of Lemma 2.30 belongs to both N_τ and $N_{\tau'}$ where τ, τ' denote the simplices spanned by ξ, ξ' . Varying ξ or ξ' yields the assertion. \square

We obtain an analogue of Corollary 2.31:

Corollary 2.38. N_h acts transitively on

- (i) every strong asymptote class of geodesics at every ideal point $\xi \in \text{int}(h)$;
- (ii) the set of maximal flats F asymptotic to h , $\partial_\infty F \supset h$.

We describe a consequence of our discussion for the horocyclic foliations.

The maximal flats asymptotic to h are contained in the parallel set $P(\partial h) \cong \mathbb{R}^{\text{rank}(X)-1} \times CS(\partial h)$ and form the leaves of a smooth foliation \mathcal{P}_h of $P(\partial h)$. This foliation is the pullback of the one-dimensional foliation of the rank one symmetric space $CS(\partial h)$ by the geodesics asymptotic to the ideal point $\zeta \in \partial_\infty CS(\partial h)$ corresponding to the center (pole) of h . We call the foliation of $P(\partial h)$ normal to \mathcal{P}_h the *horocyclic foliation* \mathcal{H}_h . Its leaves are of the form point times a horosphere in $CS(\partial h)$ centered at ζ . We call them *horocycles at h* . Corollary 2.38 implies that they are the N_h -orbits, and we denote by $Hc_x^h = N_h x$ the horocycle through the point $x \in P(\partial h)$.

Let τ be a simplex so that $\text{int}(\tau) \subset \text{int}(h)$. Then the foliation \mathcal{P}_τ of X by parallel sets restricts on $P(\partial h)$ to the foliation \mathcal{P}_h by maximal flats, and the horocyclic foliation \mathcal{H}_τ restricts to the horocyclic foliation \mathcal{H}_h . (This follows from the fact that the foliations \mathcal{P}_τ and \mathcal{H}_τ are normal to each other, cf. (2.34).) In other words, the foliations \mathcal{H}_τ for the various simplices τ coincide on the parallel set $P(\partial h)$.

2.4.5 Distances to parallel sets versus angles

In this section we collect further geometric facts regarding parallel sets in symmetric spaces, primarily dealing with estimation of distances from points in X to parallel sets.

We first strengthen Proposition 2.35:

Lemma 2.39. *Suppose that τ_\pm are antipodal simplices in $\partial_{\text{Tits}} X$. Then every geodesic ray γ asymptotic to a point $\xi \in \text{ost}(\tau_+)$, is strongly asymptotic to a geodesic ray in $P(\tau_-, \tau_+)$.*

Proof. If ξ belongs to the interior of the simplex τ_+ , then the assertion follows from Proposition 2.35. We now consider the general case. Suppose, that ξ belongs to an open simplex $\text{int}(\tau')$, such that τ is a face of τ' . Then there exists an apartment $a \subset \partial_{\text{Tits}} X$ containing both ξ (and,

hence, τ' as well as τ) and the simplex τ_- . Let $F \subset X$ be the maximal flat with $\partial_\infty F = a$. Then F contains a geodesic asymptotic to points in τ_- and τ_+ . Therefore, F is contained in $P(\tau_-, \tau_+)$. On the other hand, by the same Proposition 2.35 applied to the simplex τ' , we conclude that γ is strongly asymptotic to a geodesic ray in F . \square

The following lemma provides a quantitative strengthening of the conclusion of Lemma 2.39:

Lemma 2.40. *Let Θ be a compact subset of $\text{ost}(\tau_+)$. Then those rays $x\xi$ with $\theta(\xi) \in \Theta$ are uniformly strongly asymptotic to $P(\tau_-, \tau_+)$, i.e. $d(\cdot, P(\tau_-, \tau_+))$ decays to zero along them uniformly in terms of $d(x, P(\tau_-, \tau_+))$ and Θ .*

Proof. Suppose that the assertion of lemma is false, i.e., there exists $\epsilon > 0$, a sequence $T_i \in \mathbb{R}_+$ diverging to infinity, and a sequence of rays $\rho_i = x_i \xi_i$ with $\xi_i \in \Theta$ and $d(x_i, P(\tau_-, \tau_+)) \leq d$, so that

$$d(y, P(\tau_-, \tau_+)) \geq \epsilon, \forall y \in \rho([0, T_i]). \quad (2.41)$$

Using the action of the stabilizer of $P(\tau_-, \tau_+)$, we can assume that the points x_i belong to a certain compact subset of X . Therefore, the sequence of rays $x_i \xi_i$ subconverges to a ray $x\xi$ with $d(x, P(\tau_-, \tau_+)) \leq d$ and $\xi \in \Theta$. The inequality (2.41) then implies that the entire limit ray $x\xi$ is contained outside of the open ϵ -neighborhood of the parallel set $P(\tau_-, \tau_+)$. However, in view of Lemma 2.39, the ray $x\xi$ is strongly asymptotic to a geodesic in $P(\tau_-, \tau_+)$. Contradiction. \square

We next relate distance from points $x \in X$ to parallel sets and certain angles at x . Fix a generic point $\zeta = \zeta_{mod}$ in τ_{mod} and consider a pair of simplices τ_\pm of type τ_{mod} ; set $\zeta_\pm = \zeta(\tau_\pm)$. We begin with the following elementary observation:

Remark 2.42. We observe that the ideal points ζ_\pm are opposite, $\angle_{Tits}(\zeta_-, \zeta_+) = \pi$, if and only if they can be seen under angle $\simeq \pi$ (i.e., close to π) from some point in X . More precisely, there exists $\epsilon(\zeta_{mod})$ such that:

If $\angle_x(\zeta_-, \zeta_+) > \pi - \epsilon(\zeta_{mod})$ for some point x then ζ_\pm are opposite.

This follows from the angle comparison $\angle_x(\zeta_-, \zeta_+) \leq \angle_{Tits}(\zeta_-, \zeta_+)$ and the fact that the Tits distance between ideal points of the fixed type ζ_{mod} takes only finitely many values.

Suppose now that the simplices τ_\pm , equivalently, the ideal points ζ_\pm , are opposite. Then $\angle_x(\zeta_-, \zeta_+) = \pi$ if and only if x lies in the parallel set $P(\tau_-, \tau_+)$. Furthermore, $\angle_x(\zeta_-, \zeta_+) \simeq \pi$ if and only if x is close to $P(\tau_-, \tau_+)$, and both quantities control each other near the parallel set. More precisely:

Lemma 2.43. (i) *If $d(x, P(\tau_-, \tau_+)) \leq d$, then $\angle_x(\zeta_-, \zeta_+) \geq \pi - \epsilon(d)$ with $\epsilon(d) \rightarrow 0$ as $d \rightarrow 0$.*

(ii) *For sufficiently small ϵ , $\epsilon \leq \epsilon'(\zeta_{mod})$, we have: The inequality $\angle_x(\zeta_-, \zeta_+) \geq \pi - \epsilon$ implies that $d(x, P(\tau_-, \tau_+)) \leq d(\epsilon)$ for some function $d(\epsilon)$ which converges to 0 as $\epsilon \rightarrow 0$.*

Proof. The intersection of parabolic subgroups $P_{\tau_-} \cap P_{\tau_+}$ preserves the parallel set $P(\tau_-, \tau_+)$ and acts transitively on it. Compactness and the continuity of $\angle(\zeta_-, \zeta_+)$ therefore imply that $\pi - \angle(\zeta_-, \zeta_+)$ attains on the boundary of the tubular r -neighborhood of $P(\tau_-, \tau_+)$ a strictly

positive maximum and minimum, which we denote by $\phi_1(r)$ and $\phi_2(r)$. Furthermore, $\phi_i(r) \rightarrow 0$ as $r \rightarrow 0$. We have the estimate:

$$\pi - \phi_1(d(x, P(\tau_-, \tau_+))) \leq \angle_x(\zeta_-, \zeta_+) \leq \pi - \phi_2(d(x, P(\tau_-, \tau_+)))$$

The functions $\phi_i(r)$ are (weakly) monotonically increasing. This follows from the fact that, along rays asymptotic to ζ_- or ζ_+ , the angle $\angle(\zeta_-, \zeta_+)$ is monotonically increasing and the distance $d(\cdot, P(\tau_-, \tau_+))$ is monotonically decreasing. The estimate implies the assertions. \square

The control of $d(\cdot, P(\tau_-, \tau_+))$ and $\angle(\zeta_-, \zeta_+)$ “spreads” along the Weyl cone $V(x, \text{st}(\tau_+))$, since the latter is asymptotic to the parallel set $P(\tau_-, \tau_+)$. Moreover, the control improves, if one enters the cone far into a τ_{mod} -regular direction. More precisely:

Lemma 2.44. *Let $y \in V(x, \text{st}_\Theta(\tau_+))$ be a point with $d(x, y) \geq l$.*

(i) *If $d(x, P(\tau_-, \tau_+)) \leq d$, then*

$$d(y, P(\tau_-, \tau_+)) \leq D'(d, \Theta, l) \leq d$$

with $D'(d, \Theta, l) \rightarrow 0$ as $l \rightarrow +\infty$.

(ii) *For sufficiently small ϵ , $\epsilon \leq \epsilon'(\zeta_{mod})$, we have: If $\angle_x(\zeta_-, \zeta_+) \geq \pi - \epsilon$, then*

$$\angle_y(\zeta_-, \zeta_+) \geq \pi - \epsilon'(\epsilon, \Theta, l) \geq \pi - \epsilon(d(\epsilon))$$

with $\epsilon'(\epsilon, \Theta, l) \rightarrow 0$ as $l \rightarrow +\infty$.

Proof. The distance from $P(\tau_-, \tau_+)$ takes its maximum at the tip x of the cone $V(x, \text{st}(\tau_+))$, because it is monotonically decreasing along the rays $x\xi$ for $\xi \in \text{st}(\tau_+)$. This yields the right-hand bounds d and, applying Lemma 2.43 twice, $\epsilon(d(\epsilon))$.

Those rays $x\xi$ with uniformly τ_{mod} -regular type $\theta(\xi) \in \Theta$ are uniformly strongly asymptotic to $P(\tau_-, \tau_+)$, i.e. $d(\cdot, P(\tau_-, \tau_+))$ decays to zero along them uniformly in terms of d and Θ , see Lemma 2.40. This yields the decay $D'(d, \Theta, l) \rightarrow 0$ as $l \rightarrow +\infty$. The decay of ϵ' follows by applying Lemma 2.43 again. \square

2.5 Dynamics of transvections at infinity

2.5.1 Identifications of horocycles and contraction

We continue with the notation of section 2.4.4.

Fix a simplex $\tau \subset \partial_\infty X$. Since every leaf of the foliation \mathcal{H}_τ intersects every leaf of \mathcal{P}_τ exactly once, and the leaves of the latter foliation correspond to the flags in $C(\tau)$, we have consistent simultaneous N_τ -equivariant smooth identifications

$$Hc^\tau \xrightarrow{\cong} Hc'^\tau$$

between the horocycles at τ , and

$$Hc^\tau \xrightarrow{\cong} C(\tau)$$

of the horocycles with the open Schubert stratum $C(\tau)$. A point $x \in Hc^\tau$ corresponds to a point $x' \in Hc'^\tau$ iff they lie in the same leaf of \mathcal{P}_τ , i.e. parallel set $P(\tau, \hat{\tau})$ for a (unique) simplex $\hat{\tau}$ opposite to τ .

Let $h \subset \partial_\infty X$ be a half-apartment such that $\text{int}(\tau) \subset \text{int}(h)$. Then the horocycles at τ intersect the parallel set $P(\partial h)$ in the horocycles at h , and the identifications restrict to N_h -equivariant smooth identifications

$$Hc^h \xrightarrow{\cong} Hc'^h$$

between the horocycles at h , and

$$Hc^h \xrightarrow{\cong} C(h)$$

of the horocycles with a submanifold $C(h) \subset C(\tau)$.

We discuss now contraction-expansion properties of these identifications.

The horocycles Hc_x^h in $P(\partial h)$ isometrically project onto the horospheres $Hc_{\bar{x}}^\zeta$ in $CS(\partial h)$. Under these projections, the natural identifications $\pi_{x'x}^h : Hc_x^h \rightarrow Hc_{x'}^h$ correspond to the natural identifications $\pi_{\bar{x}'\bar{x}}^\zeta : Hc_{\bar{x}}^\zeta \rightarrow Hc_{\bar{x}'}^\zeta$ of horospheres. The cross sections $CS(\partial h)$ are rank one symmetric spaces. There are only finitely many isometry types of them occurring in X . In a rank one symmetric space, the natural identifications between horospheres contract and expand exponentially. (This follows from the fact that the exponential decay rate of decaying Jacobi fields along geodesics is bounded below and above.) We therefore obtain the following estimate for the contraction-expansion of the identifications $\pi_{x'x}^h : Hc_x^h \rightarrow Hc_{x'}^h$: If $b_\zeta(x) - b_\zeta(x') = b_\zeta(\bar{x}) - b_\zeta(\bar{x}') \geq 0$ and $x' = \pi_{x'x}^h(x)$, then for corresponding points $y \in Hc_x^h$ and $y' = \pi_{x'x}^h(y) \in Hc_{x'}^h$ we have

$$e^{-c_1 d(\bar{x}, \bar{x}')} \leq \frac{d(x', y')}{d(x, y)} \leq e^{-c_2 d(\bar{x}, \bar{x}')} \quad (2.45)$$

with constants $c_1 \geq c_2 > 0$ depending only on X .

2.5.2 Infinitesimal contraction of transvections

We describe now the action of transvections at infinity using the natural identifications of horocycles.

Suppose that $x, x' \in P(\tau, \hat{\tau})$ are distinct points. Let $\vartheta_{xx'}$ denote the transvection with axis $l_{xx'}$ through x and x' mapping $x' \mapsto x$. It preserves $\partial_\infty P(\tau, \hat{\tau}) \subset \partial_\infty X$ and fixes the singular sphere $s(\tau, \hat{\tau}) \subset \partial_\infty P(\tau, \hat{\tau})$ pointwise. In particular, it fixes the simplices τ and $\hat{\tau}$. We consider the action of $\vartheta_{xx'}$ on $C(\tau)$ and its differential at the fixed point $\hat{\tau}$. Modulo the identifications $C(\tau) \xrightarrow{\cong} Hc_x^\tau$ and $\pi_{x'x}^\tau : Hc_x^\tau \rightarrow Hc_{x'}^\tau$, the action of $\vartheta_{xx'}$ on $C(\tau)$ corresponds to the action of $\vartheta_{xx'} \pi_{x'x}^\tau$ on Hc_x^τ , and the differential of $\vartheta_{xx'}$ at $\hat{\tau}$ to the differential of $\vartheta_{xx'} \pi_{x'x}^\tau$ at x .

We first consider the case that $\vartheta_{xx'}$ translates towards $\hat{\tau}$, i.e. when $\xi := l_{xx'}(-\infty) \in \text{ost}(\tau)$, equivalently, when x' lies in the interior of the Weyl cone $V(x, \text{st}(\tau))$.

Lemma 2.46. *If $\xi \in \text{ost}(\tau)$, then $(d\vartheta_{xx'})_{\hat{\tau}}$ is diagonalizable with strictly positive eigenvalues.*

Proof. If $\xi \in \text{ost}(\tau)$, then there is a natural N_τ -equivariant identification of $C(\tau)$ with the strong asymptote class of the geodesic $l_{xx'}$. Namely, the simplex $\hat{\tau}' \in C(\tau)$ corresponds to the unique geodesic $l' \subset P(\tau, \hat{\tau}')$ strongly asymptotic to $l_{xx'}$, and in particular $\hat{\tau}$ corresponds to $l_{xx'}$. Accordingly, tangent vectors to $C(\tau)$ at $\hat{\tau}$ one-to-one correspond to Jacobi fields along $l_{xx'}$ which are orthogonal to $P(\tau, \hat{\tau})$ and decay to zero at ξ . The effect of the differential $(d\vartheta_{xx'})_{\hat{\tau}}$ on $C(\tau)$ is given in terms of these Jacobi fields J by

$$J \mapsto d\vartheta_{xx'} \circ J \circ \vartheta_{x'x}$$

The Jacobi fields, which are of the form exponential function times a parallel vector field along $l_{xx'}$, correspond to eigenvectors of the differential of $\vartheta_{x'x}$ with strictly positive eigenvalues. It is a standard fact from the Riemannian geometry of symmetric spaces that every decaying Jacobi field (orthogonally) decomposes as a sum of such special Jacobi fields. (One trivializes the normal bundle along the geodesic using the one parameter group of transvections along it. Since the curvature tensor of a Riemannian symmetric space is parallel, the Jacobi equation becomes an ODE with constant coefficients.) Thus the eigenvectors of $(d\vartheta_{xx'})_{\hat{\tau}}$ for positive eigenvalues span $T_{\hat{\tau}}C(\tau)$. \square

Lemma 2.47. *If $\xi \in \text{ost}(\tau)$, then the eigenvalues λ of $(d\vartheta_{xx'})_{\hat{\tau}}$ satisfy an estimate*

$$-\log \lambda \geq c \cdot d(x', \partial V(x, \text{st}(\tau)))$$

with a constant $c > 0$ depending only on X .

Proof. We continue the argument in the previous proof.

Let $F \supset l_{xx'}$ be a maximal flat. Then $F \subset P(\tau, \hat{\tau})$. A smooth variation of the geodesic $l_{xx'}$ by strongly asymptotic geodesics extends to a smooth variation of F by maximal flats asymptotic to $\text{st}(\tau) \cap \partial_\infty F$. Indeed, it can be induced by a smooth curve in N_τ through 1, and this curve can be used to vary F .

The Jacobi field J along $l_{xx'}$ corresponding to a tangent vector $v \in T_{\hat{\tau}}C(\tau)$ therefore extends to a Jacobi field \hat{J} along F which decays to zero at all ideal points $\eta \in \text{ost}(\tau) \cap \partial_\infty F$. The decomposition of Jacobi fields on symmetric spaces mentioned in the previous proof works in the same way along flats. (One trivializes the normal bundle using the abelian transvection subgroup.) Hence \hat{J} decomposes as an orthogonal sum of Jacobi fields along F of the form $e^{-\alpha}V$ with an affine linear form α on F and a parallel orthogonal vector field V along F . Up to additive constants, only finitely many affine linear forms α occur, since G acts transitively on maximal flats. (The possible forms are determined by the root system of G , but we do not need this fact here.)

We may normalize the forms α occurring in our decomposition so that $\alpha(x) = 0$. Since \hat{J} decays to zero at $\text{ost}(\tau) \cap \partial_\infty F$, they have the property that $\alpha \geq 0$ on $V(x, \text{st}(\tau) \cap \partial_\infty F)$, equivalently, that $\text{st}(\tau) \cap \partial_\infty F \subset \partial_\infty \{\alpha \geq 0\}$. Moreover, $\alpha > 0$ on the interior of the cone $V(x, \text{st}(\tau) \cap \partial_\infty F)$, because $\alpha \neq 0$. One can estimate

$$\alpha(x') \geq c(\alpha) \cdot d(x', \partial V(x, \text{st}(\tau)))$$

with a constant $c(\alpha) > 0$. Taking c to be the minimum over the finitely many constants $c(\alpha)$, we obtain the assertion, because the eigenvalues of $(d\vartheta_{xx'})_{\hat{\tau}}$ are bounded above by the maximal possible value of $e^{-\alpha(x')}$. \square

The previous two lemmas yield:

Corollary 2.48. *If $x' \in V(x, \text{st}(\tau))$, then $(d\vartheta_{xx'})_{\hat{\tau}}$ is weakly contracting on $T_{\hat{\tau}}C(\tau)$ with norm*

$$\|(d\vartheta_{xx'})_{\hat{\tau}}\| \leq e^{-c \cdot d(x', \partial V(x, \text{st}(\tau)))}$$

where the constant $c > 0$ depends only on X . In particular, it is strongly contracting if x' lies in the interior of $V(x, \text{st}(\tau))$.

Proof. For x' in the interior of the Weyl cone, and hence $\xi \in \text{ost}(\tau)$, this is a direct consequence. For x' on the boundary of the cone, it follows by continuity. \square

In order to show that $\vartheta_{xx'}$ has expanding directions at $\hat{\tau}$ if x' lies outside the Weyl cone, we consider its action on certain invariant submanifolds of $C(\tau)$ corresponding to parallel sets of singular hyperplanes.

Let again F be a maximal flat with $l_{xx'} \subset F \subset P(\tau, \hat{\tau})$. Moreover, let $h \subset \partial_{\infty}F$ be a half-apartment such that $\text{int}(\tau) \subset \text{int}(h)$. Then $\vartheta_{xx'}$ fixes $\partial_{\infty}F$ pointwise. Hence it preserves h , the parallel set $P(\partial h)$ and the submanifold $C(h) = N_h \hat{\tau} \subset C(\tau)$.

If $l_{xx'}$ is parallel to the euclidean factor of $P(\partial h)$, equivalently, if $\xi \in \partial_{\infty}l_{xx'} \subset \partial h$, then $\vartheta_{xx'}$ acts trivially on the cross section $CS(\partial h)$, and hence also trivially on $C(h) \cong \partial_{\infty}CS(\partial h) - \{\zeta\}$.

In the general case, the action of $\vartheta_{xx'}$ on $C(h)$ corresponds to the restriction of the action of $\vartheta_{xx'}\pi_{x'x}^{\tau}$ to $Hc_x^h = Hc_x^{\tau} \cap P(\partial h)$. When projecting to $CS(\partial h)$, the latter action in turn corresponds to the action of $\vartheta_{\bar{x}\bar{x}'}\pi_{\bar{x}'\bar{x}}^{\zeta}$ on $Hc_{\bar{x}}^{\zeta}$. Here, $\vartheta_{\bar{x}\bar{x}'}$ denotes the transvection on $CS(\partial h)$ with axis $l_{\bar{x}\bar{x}'}$ through \bar{x} and \bar{x}' mapping $\bar{x}' \mapsto \bar{x}$, and $\pi_{\bar{x}'\bar{x}}^{\zeta} : Hc_{\bar{x}}^{\zeta} \rightarrow Hc_{\bar{x}'}^{\zeta}$ denotes the natural identification of horospheres at ζ . The projection of F to $CS(\partial h)$ is a $\vartheta_{\bar{x}\bar{x}'}$ -invariant geodesic line asymptotic to ζ and another ideal point $\hat{\zeta}$. The fixed point $\hat{\tau}$ of $\vartheta_{xx'}$ on $C(\tau)$ corresponds to the fixed point $\hat{\zeta}$ of $\vartheta_{\bar{x}\bar{x}'}$ on $\partial_{\infty}CS(\partial h) - \{\zeta\}$.

We prove analogues of Lemmata 2.46 and 2.47.

Lemma 2.49. *If $\xi \in \text{int}(h)$, then the restriction of the differential of $\vartheta_{xx'}$ at $\hat{\tau}$ to the invariant subspace $T_{\hat{\tau}}C(h) \subset T_{\hat{\tau}}C(\tau)$ is diagonalizable with strictly positive eigenvalues.*

Proof. Modulo the canonical identification $C(h) \cong \partial_{\infty}CS(\partial h) - \{\zeta\}$, $\vartheta_{xx'}$ restricts to $\vartheta_{\bar{x}\bar{x}'}$. The argument for $\vartheta_{\bar{x}\bar{x}'}$ on $\partial_{\infty}CS(\partial h)$ is then the same as for Lemma 2.46. We have that $\zeta = l_{\bar{x}\bar{x}'}(-\infty)$ because $\xi \in \text{int}(h)$. Therefore, the tangent vectors to $C(h)$ at $\hat{\zeta}$ one-to-one correspond to the orthogonal Jacobi fields along $l_{\bar{x}\bar{x}'}$ which decay to zero at ζ . We conclude as before that $(d\vartheta_{\bar{x}\bar{x}'})_{\hat{\zeta}}$ is diagonalizable with strictly positive eigenvalues. \square

Lemma 2.50. *If $\xi \in \text{int}(h)$, then the eigenvalues λ of $(d\vartheta_{xx'})_{\hat{\tau}}|_{T_{\hat{\tau}}C(h)}$ satisfy an estimate*

$$c_1 \leq \frac{-\log \lambda}{b_{\zeta}(x) - b_{\zeta}(x')} \leq c_2 \tag{2.51}$$

with constants $c_1, c_2 > 0$ depending only on X .

Proof. Since $\xi \in \text{int}(h)$, we have that $b_\zeta(x) - b_\zeta(x') = d(\bar{x}, \bar{x}') > 0$. The assertion follows from the contraction estimate (2.45) and the diagonalizability of the differential. \square

Corollary 2.52. *If $x' \in P(\tau, \hat{\tau}) - V(x, \text{st}(\tau))$, then $(d\vartheta_{xx'})_{\hat{\tau}}$ is not weakly contracting on $T_{\hat{\tau}}C(\tau)$.*

Proof. By our assumption, we have that $\xi \notin \text{st}(\tau)$. Therefore, the half-apartment $h \subset \partial_\infty F$ can be chosen so that its interior contains, besides $\text{int}(\tau)$, also $l_{xx'}(+\infty)$. (Recall that the convex subcomplex $\text{st}(\tau) \cap \partial_\infty F$ is an intersection of half-apartments in $\partial_\infty F$.) Then the estimate (2.51) applied to $\vartheta_{x'x} = \vartheta_{xx'}^{-1}$ yields that $(d\vartheta_{xx'})_{\hat{\tau}}^{-1}$ has eigenvalues in $(0, 1)$. \square

We also can deduce an upper estimate on the strength of the contraction if $x' \in V(x, \text{st}(\tau))$, complementing Lemma 2.47:

Lemma 2.53. *If $\xi \in \text{st}(\tau)$, then $(d\vartheta_{xx'})_{\hat{\tau}}$ has an eigenvalue satisfying an estimate*

$$-\log \lambda \leq C \cdot d(x', \partial V(x, \text{st}(\tau)))$$

with a constant $C > 0$ depending only on X .

Proof. A nearest point y' to x' on $\partial V(x, \text{st}(\tau))$ lies on $\partial V(x, \text{st}(\tau)) \cap F = \partial V(x, \text{st}(\tau) \cap \partial_\infty F)$. Hence we can choose the half-apartment h so that $b_\zeta(y') = b_\zeta(x)$ and

$$d(x', \partial V(x, \text{st}(\tau))) = b_\zeta(x) - b_\zeta(x').$$

Now let λ be an eigenvalue of $(d\vartheta_{xx'})_{\hat{\tau}}|_{T_{\hat{\tau}}C(h)}$ and apply the upper estimate (2.51). \square

Putting the information (Corollaries 2.48, 2.52 and Lemma 2.53) together, we obtain:

Theorem 2.54 (Infinitesimal contraction of transvections at infinity). *Let $\tau, \hat{\tau} \subset \partial_\infty X$ be a pair of opposite simplices, and let ϑ be a nontrivial transvection which has an axis $c \subset P(\tau, \hat{\tau})$ through the point $x = c(0)$. Then the following hold for the differential $d\vartheta_{\hat{\tau}}$ of ϑ on $C(\tau)$ at the fixed point $\hat{\tau}$:*

(i) *$d\vartheta_{\hat{\tau}}$ is weakly contracting on $T_{\hat{\tau}}C(\tau)$, if and only if $\vartheta^{-1}x \in V(x, \text{st}(\tau))$, and strongly contracting if and only if $\vartheta^{-1}x \in \text{int}(V(x, \text{st}(\tau)))$.*

(ii) *Suppose that $\vartheta^{-1}x \in V(x, \text{st}(\tau))$. Then the exponential contraction rate of $d\vartheta_{\hat{\tau}}$ is comparable to $d(\vartheta^{-1}x, \partial V(x, \text{st}(\tau)))$, i.e. there is an estimate*

$$c_1 \cdot d(\vartheta^{-1}x, \partial V(x, \text{st}(\tau))) \leq -\log \|d\vartheta_{\hat{\tau}}\| \leq c_2 \cdot d(\vartheta^{-1}x, \partial V(x, \text{st}(\tau)))$$

with constants $c_1, c_2 > 0$ depending only on X .

We will later use the following consequence of the theorem for general isometries in G .

Corollary 2.55 (Infinitesimal expansion of isometries at infinity). *Let $\tau \subset \partial_\infty X$ be a simplex of type τ_{mod} , $x \in X$ a point and $g \in G$ an isometry such that $d(gx, V(x, \text{st}(\tau))) < r$.*

Then the exponential expansion rate $\log \epsilon(g^{-1}, \tau)$ of g^{-1} on $\text{Flag}(\tau_{mod})$ at τ is comparable to $d(gx, \partial V(x, \text{st}(\tau)))$ in the sense that

$$C^{-1} \cdot d(gx, \partial V(x, \text{st}(\tau))) - A \leq \log \epsilon(g^{-1}, \tau) \leq C \cdot d(gx, \partial V(x, \text{st}(\tau))) + A$$

with constants $C, A > 0$ depending only on X, r and the chosen background Riemannian metric on $\text{Flag}(\tau_{mod})$.

Proof. We can write the isometry g as a product $g = tb$ of a transvection t along a geodesic l through x asymptotic to $\text{st}(\tau)$, $l(+\infty) \in \text{st}(\tau)$, and an isometry $b \in G$ which is bounded in terms of the radius r . Then t fixes τ on $\text{Flag}(\tau_{mod})$, and the expansion factor $\epsilon(g^{-1}, \tau)$ equals $\epsilon(t^{-1}, \tau)$ up to a multiplicative constant depending on X, r and the background Riemannian metric on $\text{Flag}(\tau_{mod})$. Furthermore, $\epsilon(t^{-1}, \tau) = \|dt_\tau\|^{-1}$.

Let $\hat{\tau}$ denote the simplex opposite to τ with respect to x . Applying Theorem 2.54(ii) to $t = \vartheta^{-1}$ while exchanging the roles of τ and $\hat{\tau}$, we obtain that the exponential contraction rate of dt_τ is comparable to $d(t^{-1}x, \partial V(x, \text{st}(\hat{\tau}))) = d(tx, \partial V(x, \text{st}(\tau)))$, i.e.:

$$c_1 \cdot d(tx, \partial V(x, \text{st}(\tau))) \leq -\log \|dt_\tau\| \leq c_2 \cdot d(tx, \partial V(x, \text{st}(\tau)))$$

Since $d(gx, tx) = d(bx, x)$ is bounded in terms of r and X , the assertion follows. \square

3 Topological dynamics preliminaries

In this section we collect various definitions and results from topological dynamics; most of them are rather standard but some are new.

Throughout this section, we let Γ be a discrete group, i.e. a group equipped with the discrete topology. We say that a sequence (γ_n) of elements of the discrete group Γ *diverges to infinity*, $\gamma_n \rightarrow \infty$, if the map $\mathbb{N} \rightarrow \Gamma, n \mapsto \gamma_n$ is proper. We consider continuous actions $\Gamma \curvearrowright Z$ on compact metric spaces (Z, d) .

3.1 Expanding actions

The following notion due to Sullivan [Su, §9] will be of basic importance to us:

Definition 3.1 (Expanding action). We say that the action $\Gamma \curvearrowright Z$ is *expanding* at the point $z \in Z$ if there exists an element $\gamma \in \Gamma$ which is *uniformly expanding* on a neighborhood U of z , i.e. for some constant $c > 1$ and all points $z_1, z_2 \in U$ we have

$$d(\gamma z_1, \gamma z_2) \geq c \cdot d(z_1, z_2).$$

We say that the action of Γ is *expanding* at a compact Γ -invariant subset $E \subset Z$ if it is expanding at all points $z \in E$.

3.2 Convergence actions

Let Z be a compact metric space. We define the space $\text{Trip}(Z)$ to be the subset of Z^3 consisting of triples of pairwise distinct points in Z . Every topological action $\Gamma \curvearrowright Z$ induces a topological action $\Gamma \curvearrowright \text{Trip}(Z)$.

Definition 3.2 (Convergence action). The action $\Gamma \curvearrowright Z$ is called a *convergence action* and the image of Γ in $\text{Homeo}(Z)$ is said to be a *convergence group* if one of the following equivalent conditions holds:

- (i) The action $\Gamma \curvearrowright \text{Trip}(Z)$ is properly discontinuous.
- (ii) For every sequence $\gamma_n \rightarrow \infty$ in Γ there exist points $z_{\pm} \in Z$ and a subsequence of (γ_n) which converges to the constant map $\equiv z_+$ uniformly on compacts in $Z - \{z_-\}$. The points z_+ and z_- are called the *limit point* and the *exceptional point* of this subsequence.

A convergence action $\Gamma \curvearrowright Z$ is said to be *uniform* if the action $\Gamma \curvearrowright \text{Trip}(Z)$ is cocompact.

A proof for the equivalence of both definitions can be found in [Bo99].

The main example of convergence actions comes from the following fact: Every discrete group Γ of isometries of a proper Gromov hyperbolic geodesic metric space X acts as a convergence group on the Gromov boundary $\partial_{\infty}X$ of X . Furthermore, every word hyperbolic group Γ acts on its Gromov boundary $\partial_{\infty}\Gamma$ as a uniform convergence group.

Bowditch proved that, vice versa, this dynamical behavior characterizes the natural actions of word hyperbolic groups on their boundaries:

Theorem 3.3 ([Bo98, Thm. 0.1]). *Let $\Gamma \curvearrowright Z$ be a uniform convergence action on a non-empty perfect compact metric space. Then Γ is word hyperbolic and Z is equivariantly homeomorphic to $\partial_{\infty}\Gamma$.*

The uniformity of a convergence action is in turn equivalent to all points being conical. The notion of conical limit point (e.g. of a Kleinian group) can be expressed purely in terms of the dynamics at infinity and, therefore, extends to the more general context considered here:

Definition 3.4 (Intrinsically conical [Bo98, §8]). Let $\Gamma \curvearrowright Z$ be a convergence action. A point $z \in Z$ is called *intrinsically conical* if there exists a sequence $\gamma_n \rightarrow \infty$ in Γ such that the sequence of points $\gamma_n^{-1}z$ converges and the sequence of maps $\gamma_n^{-1}|_{Z-\{z\}}$ converges (uniformly on compacta) to a constant map with value $\neq \lim_{n \rightarrow \infty} \gamma_n^{-1}z$.

We note that the locally uniform convergence of $\gamma_n^{-1}|_{Z-\{z\}}$ to a constant map implies that z is a limit point of Γ . We, thus, will refer to such point z as an *intrinsically conical limit point* of Γ .

Theorem 3.5 ([Bo98, Thm. 8.1], [Tu98]). *A convergence action $\Gamma \curvearrowright Z$ on a perfect compact metric space Z is uniform if and only if every point in Z is intrinsically conical.*

Remark 3.6. The easy direction is that uniformity implies conicality. This can be seen as

follows: Let $z' \neq z$ and $z_n'' \rightarrow z$ be a sequence of points different from z . By uniformity, there exist elements $\gamma_n \rightarrow \infty$ in Γ such that we have convergence $\gamma_n^{-1}z \rightarrow z_\infty$, $\gamma_n^{-1}z' \rightarrow z'_\infty$ and $\gamma_n^{-1}z_n'' \rightarrow z''_\infty$ with pairwise different limits. Since $\Gamma \curvearrowright Z$ is a convergence action, we have convergence of γ_n^{-1} to a constant map on $Z - \{z\}$ or on $Z - \{z'\}$. The latter is impossible because the convergence is locally uniform and $\gamma_n^{-1}z_n'' \rightarrow z''_\infty \neq z_\infty$. Thus, the point z is intrinsically conical.

The following result connects expanding actions with Bowditch's theorem. Note that if we equip the boundary of a word hyperbolic group Γ with a visual metric d , then the natural action $\Gamma \curvearrowright (\partial_\infty \Gamma, d)$ is expanding, see e.g. [CP].

Lemma 3.7. *If $\Gamma \curvearrowright Z$ is an expanding convergence action on a perfect compact metric space Z , then all points in Z are intrinsically conical.*

Proof. We start with a general remark concerning expanding actions. For every point $z \in Z$ there exist an element $\gamma \in \Gamma$ and constants $r > 0$ and $c > 1$ such that γ is a c -expansion on the ball $B(z, r)$ and $\gamma(B(z, r')) \supset B(\gamma z, cr')$ for all radii $r' \leq r$. To see this, suppose that c is a local expansion factor for γ at z and, by contradiction, that there exist sequences of radii $r_n \rightarrow 0$ and points $z_n \notin B(z, r_n)$ such that $\gamma z_n \in B(\gamma z, cr_n)$. Then $z_n \rightarrow z$ due to the continuity of γ^{-1} and, for large n , we obtain a contradiction to the local c -expansion of γ . Since Z is compact, the constants r and c can be chosen uniformly. It follows by iterating expanding maps that for every point z and every neighborhood V of z there exists $\gamma \in \Gamma$ such that $\gamma(V) \supset B(\gamma z, r)$, equivalently, $\gamma(Z - V) \subset Z - B(\gamma z, r)$.

To verify that a point z is intrinsically conical, let V_n be a shrinking sequence of neighborhoods of z ,

$$\bigcap_n V_n = \{z\},$$

and let $\gamma_n \in \Gamma$ be elements such that $\gamma_n^{-1}(Z - V_n) \subset Z - B(\gamma_n^{-1}z, r)$. Since V_n is shrinking and $\gamma_n^{-1}(V_n) \supset B(\gamma_n^{-1}z, r)$ contains balls of uniform radius r , it follows that the γ_n^{-1} do not subconverge uniformly on any neighborhood of z ; here we use that Z is perfect. In particular, $\gamma_n \rightarrow \infty$. The convergence action property implies that, after passing to a subsequence, the γ_n^{-1} must converge locally uniformly on $Z - \{z\}$. Moreover, we can assume that the sequence of points $\gamma_n^{-1}z$ converges. By construction, its limit will be different (by distance $\geq r$) from the limit of the sequence of maps $\gamma_n^{-1}|_{Z - \{z\}}$. Hence the point z is intrinsically conical. \square

Suppose that $\Gamma \curvearrowright Z$ is a convergence action. The set of limit points of sequences in Γ is called the *limit set* $\Lambda(\Gamma)$ of Γ ; the limit set can be also described as the set of exceptional points of sequences in Γ . The group Γ is called *elementary* if $\Lambda(\Gamma)$ contains at most 2 points and *nonelementary* otherwise.

We will need the following theorem, proven in the case of groups acting on spheres by Gehring and Martin [GeM, Theorem 6.3] and by Tukia [Tu94, Theorem 2S] in general:

Theorem 3.8. *If Γ is nonelementary then the action of Γ on its limit set $\Lambda(\Gamma)$ is minimal and $\Lambda(\Gamma)$ is perfect.*

4 Convex cocompact groups of isometries of rank one symmetric spaces

In this section we review equivalent definitions and properties of convex cocompact groups of isometries of negatively curved symmetric spaces. Most of this discussion remains valid in the case of isometry groups of proper $CAT(-1)$ spaces. The main reference for this material is the paper of Bowditch [Bo95]. We also refer the reader to [Ka] for a survey of discrete isometry groups of rank one symmetric spaces (primarily focused on higher-dimensional real-hyperbolic spaces).

Let $\Gamma \subset G = \text{Isom}(X)$ be a discrete subgroup of the group of isometries of a negatively curved symmetric space X . We let $\Lambda = \Lambda(\Gamma) \subset \partial_\infty X$ denote the *limit set* of Γ , i.e. the accumulation set of a Γ -orbit in X . Note that Λ is necessarily closed in $\partial_\infty X$. Then $\Omega = \Omega(\Gamma) = \partial_\infty X - \Lambda$ is the *domain of discontinuity* of Γ , which is also the wandering set for the action $\Gamma \curvearrowright \partial_\infty X$, and hence is the largest open subset of $\partial_\infty X$ where Γ acts properly discontinuously. The *Nielsen hull* $N(\Lambda)$ of Λ is defined as the smallest closed convex subset in X whose ideal boundary contains Λ . The set $N(\Lambda)$ exists provided that Λ contains at least two points; in this case, $\partial_\infty N(\Lambda) = \Lambda$. In what follows, we will consider only *nonelementary* discrete subgroups Γ , i.e., subgroups for which $\Lambda(\Gamma)$ contains more than 2 points.

The following definition explains the terminology *convex cocompact*.

Definition 4.1 (C1). A discrete subgroup $\Gamma \subset G$ is called *convex cocompact* if $N(\Lambda(\Gamma))/\Gamma$ is compact.

In particular, such group Γ is finitely presented and, moreover, word hyperbolic.

A limit point $\lambda \in \Lambda$ is called a *conical limit point* of Γ if for some (every) geodesic ray ρ in X asymptotic to λ there exists a sequence $\gamma_i x \subset X$ converging to λ in an R -neighborhood of ρ for some $R < \infty$.

Definition 4.2 (C2). A discrete subgroup $\Gamma \subset G$ is called *convex cocompact* if every limit point of Γ is conical.

In fact, one can get R to be uniform for $x \in N(\Lambda)$ and $\lambda \in \Lambda$.

Recall (see section 3.2) that for a set Z , $\text{Trip}(Z)$ denotes the set of triples of pairwise distinct points in Z .

Definition 4.3 (C3). A discrete subgroup $\Gamma \subset G$ is called *convex cocompact* if the action $\Gamma \curvearrowright \text{Trip}(\Lambda)$ is cocompact.

Every discrete group $\Gamma \subset G$ acts properly discontinuously on $X \cup \Omega$, which we equip with the subset topology induced from $\bar{X} = X \cup \partial_\infty X$.

Definition 4.4 (C4). A discrete subgroup $\Gamma \subset G$ is called *convex cocompact* if the action $\Gamma \curvearrowright X \cup \Omega$ is cocompact.

Definition C4 implies that for every convex cocompact subgroup $\Gamma \subset G$, the quotient Ω/Γ is compact. The converse is false, as the following examples show.

Example 4.5. 1. Consider a cyclic group Γ of parabolic isometries of the hyperbolic plane $\mathbb{H}^2 = X$. Then $\Lambda(\Gamma)$ is a singleton, Ω/Γ is homeomorphic to S^1 , while

$$(X \cup \Omega)/\Gamma \cong [0, \infty) \times S^1$$

is noncompact. Thus, Γ is not convex cocompact. In this case, of course, Γ contains unipotent (parabolic) elements. The next three examples contain only loxodromic elements.

2. Let S denote a closed hyperbolic surface, $\pi := \pi_1(S)$. Then π admits a discrete and faithful representation $\rho : \pi \rightarrow G = \text{Isom}(\mathbb{H}^3)$, so that its image $\Gamma = \rho(\pi)$ is a *totally-degenerate purely loxodromic subgroup* of G : $\Omega(\Gamma)$ is simply connected and nonempty, Γ contains no parabolic elements and

$$(X \cup \Omega)/\Gamma$$

is homeomorphic to $S \times [0, \infty)$, where $S \times \{0\}$ corresponds to Ω/Γ , see [Be]. Thus, Γ is not convex cocompact.

3. Let M be a closed oriented hyperbolic m -manifold with a nonseparating oriented closed totally-geodesic hypersurface N . Such manifolds exist for all m (see [Mil]). Let $\tilde{M} \rightarrow M$ denote the infinite cyclic cover determined by the homomorphism $\pi_1(M) \rightarrow \mathbb{Z}$ corresponding to the element of $H^1(M, \mathbb{Z})$ Poincaré dual to the homology class $[N]$. Then N lifts to a submanifold $N_0 \subset \tilde{M}$ which is isometric to N and which separates \tilde{M} in two components \tilde{M}_-, \tilde{M}_+ . Let M' denote the metric completion of the Riemannian manifold \tilde{M}_+ . Then M' is a complete hyperbolic manifold with single geodesic boundary component isometric to N_0 and injectivity radius bounded below. The fundamental group Γ of M' is not finitely generated. The hyperbolic structure on M' determines a discrete isometric action $\Gamma \curvearrowright \mathbb{H}^m$, so that Γ contains no parabolic elements. Then

$$(\mathbb{H}^m \cup \Omega)/\Gamma$$

is homeomorphic to M' . In particular, Ω/Γ is compact and nonempty, while Γ is not even finitely generated; in particular, Γ is not convex cocompact.

4. Similarly, for every simple Lie group G of rank 1, there are discrete subgroups $\Gamma \subset G$ whose limit set is the entire sphere $\partial_\infty X$, but Γ is not finitely generated. For instance, one can start with a uniform lattice $\hat{\Gamma} \subset G$; being a non-elementary word hyperbolic group, $\hat{\Gamma}$ admits a normal subgroup Γ which is isomorphic to the free groups of countably infinite rank. The limit set of Γ is necessarily the entire sphere $\partial_\infty X$. Furthermore, when X is a real-hyperbolic 3-space or complex-hyperbolic plane or complex-hyperbolic 3-space, there are examples of finitely generated subgroups $\Gamma \subset G$ whose limit set is $\partial_\infty X$, but Γ is not a lattice in G . In the case $X = \mathbb{H}^3$, such examples can be constructed, for instance, using normal surface subgroups in fundamental groups of closed hyperbolic 3-manifolds fibering over the circle. For examples in $\mathbb{C}\mathbb{H}^2$ and $\mathbb{C}\mathbb{H}^3$ see e.g. [Ka13]: These are normal subgroups in complex-hyperbolic manifolds which admit (singular) holomorphic fibrations over hyperbolic Riemann surfaces.

On the other hand, the phenomenon in the Examples 2 and 3 can essentially only occur in the real-hyperbolic case:

Theorem 4.6 (See [Ra]). *Let X be a negatively curved rank one symmetric space which is not real-hyperbolic. Suppose that $\Gamma \subset G = \text{Isom}(X)$ is a discrete torsion-free subgroup without unipotent elements so that $\Omega(\Gamma)/\Gamma$ is compact and nonempty. Then Γ is convex cocompact provided that X is not isometric to $\mathbb{C}\mathbb{H}^2$. In the case $X = \mathbb{C}\mathbb{H}^2$, the same result holds provided that the Riemannian manifold X/Γ has injectivity radius bounded below.*

Let $\Gamma \subset G$ be a discrete subgroup. Pick a point $x \in X$ which is not fixed by any nontrivial element of Γ , and define the *Dirichlet fundamental domain* D_x of Γ as

$$D_x = \{y \in X : d(x, y) \leq d(\gamma x, y), \forall \gamma \in \Gamma\}.$$

Note that D_x is convex if X is real-hyperbolic, but is not convex otherwise. In general, D_x is starlike with the center x ; since X is Gromov hyperbolic, this implies that D_x is *quasiconvex* in X . Subsets of D_x of the form

$$D_x \cap \gamma D_x, \quad \gamma \in \Gamma,$$

are called *faces* of D_x .

Let \bar{D}_x denote the union

$$D_x \cup (\partial_\infty D_x \cap \Omega(\Gamma)),$$

which is a certain partial compactification of D_x . It follows (almost) immediately from C4 that Γ is convex cocompact if and only if \bar{D}_x is compact. The following definition is a more elaborate version of this observation:

Definition 4.7 (C5). A discrete subgroup $\Gamma \subset G$ containing no parabolic elements is called *convex cocompact* if one (every) Dirichlet fundamental domain D_x has finitely many faces.

Note that a cyclic unipotent subgroup of $\text{Isom}(\mathbb{H}^4)$ can have a Dirichlet domain with infinitely many faces.

Definition 4.8 (C6). A discrete subgroup $\Gamma \subset G$ is convex cocompact whenever Γ is word hyperbolic as an abstract group and there exists an equivariant homeomorphism

$$\beta : \partial_\infty \Gamma \rightarrow \Lambda(\Gamma),$$

where $\partial_\infty \Gamma$ is the Gromov boundary of Γ .

Note that the injectivity of β is critical here:

Theorem 4.9 (Mj, [M1, M2]). *Suppose that $\Gamma \subset \text{Isom}(\mathbb{H}^3)$ is a word hyperbolic subgroup (not necessarily convex cocompact). Then there always exists a continuous equivariant map $\beta : \partial_\infty \Gamma \rightarrow \Lambda(\Gamma)$; the map β is called the Cannon-Thurston map for the subgroup $\Gamma \subset G$.*

Let $\Gamma \subset G$ be a finitely generated subgroup of a Lie group G with finitely many connected components; we will equip Γ with a word metric. A point $x \in X$ defines the *orbit map*

$\Gamma \rightarrow \Gamma x \subset X$. The subgroup Γ is called *undistorted* in G , if some (any) orbit map $\Gamma \rightarrow X$ is a quasi-isometric embedding, equivalently, if the inclusion $\Gamma \rightarrow G$ is a quasi-isometric embedding, where G is equipped with a left invariant Riemannian metric.

Definition 4.10 (C7). A discrete subgroup $\Gamma \subset G$ is convex cocompact if it is undistorted.

Note that, in view of the hyperbolicity of X , undistortion of Γ implies that the quasi-isometrically embedded Γ -orbits are quasi-convex subsets of X . In particular:

1. Γ is word hyperbolic, and hence the orbit maps $\Gamma \rightarrow \Gamma x$ continuously extend at infinity to an equivariant homeomorphism $\beta : \partial_\infty \Gamma \rightarrow \Lambda(\Gamma)$.
2. The Γ -equivariant relation in $X \times \Gamma$ given by the nearest-point projection to an orbit Γx is a coarse Lipschitz retraction $X \rightarrow \Gamma x$.

The converse to this is also easy:

Definition 4.11 (C8). A discrete subgroup $\Gamma \subset G$ is convex cocompact if for some (every) Γ -orbit $\Gamma x \subset X$ there exists a Γ -equivariant coarse Lipschitz retraction $X \rightarrow \Gamma x$.

The equivariance condition for the retraction can be omitted:

Definition 4.12 (C9). A discrete subgroup $\Gamma \subset G$ is convex cocompact if for some (every) Γ -orbit $\Gamma x \subset X$ there exists a coarse Lipschitz retraction $X \rightarrow \Gamma x$.

Our last characterization of convex cocompactness is in terms of expanding actions. We fix a visual metric d on $S = \partial_\infty X$.

Definition 4.13 (C10). A discrete subgroup $\Gamma \subset G$ is convex cocompact if its action on $\partial_\infty X$ is expanding at every point of $\Lambda(\Gamma)$, see Definition 3.1.

This interpretation of convex cocompactness appears in Sullivan's paper [Su].

Theorem 4.14. *The definitions C1–C10 are equivalent.*

The equivalence of Definitions C1–C9 can be found for instance in [Bo95]. The implication C10 \Rightarrow C2 is a corollary of Lemma 3.7. In the case of real-hyperbolic space, the implication C5 \Rightarrow C10 is immediate by taking a Ford fundamental domain (bounded by finitely many isometric spheres $I(\gamma_i), I(\gamma_i^{-1}), i = 1, \dots, k$) and observing that γ_i is a strict expansion on every compact contained in the open round ball bounded by $I(\gamma_i)$. For the remaining rank one symmetric spaces the implication C2 \Rightarrow C10 is a corollary of our Proposition 6.10 in section 6.1.5.

5 Weakly regular subgroups and their limit sets

5.1 Weak regularity

In this section we introduce and discuss an asymptotic regularity property for discrete subgroups Γ of a semisimple group G . It is a condition on the asymptotics of divergent sequences in the subgroup and is defined with respect to a ι -invariant face type $\tau_{mod} \subset \sigma_{mod}$.

We first define a stronger *uniform* version of regularity which can be stated more directly in terms of the limit set $\Lambda(\Gamma) = \overline{\Gamma x} \cap \partial_\infty X$ in the visual boundary.

We recall that the subset of τ_{mod} -regular types in σ_{mod} is the *open star* $\text{ost}(\tau_{mod})$, that is, the union of all open faces of σ_{mod} which contain τ_{mod} in their closure, see section 2.4.2. The τ_{mod} -regular part of the ideal boundary is then defined as the subset

$$\partial_\infty^{\tau_{mod}\text{-reg}} X = \theta^{-1}(\text{ost}(\tau_{mod})) \subset \partial_\infty X$$

of all τ_{mod} -regular ideal points. It consists of the ideal points for which there is a unique closest (with respect to the Tits metric) simplex $\tau \subset \partial_\infty X$ of type τ_{mod} . It contains all open chambers and is in particular dense in $\partial_\infty X$ (also in the Tits topology).

Definition 5.1 (Uniformly weakly regular). We call the subgroup Γ *uniformly τ_{mod} -regular* if its visual limit set consists only of τ_{mod} -regular ideal points, $\Lambda(\Gamma) \subset \partial_\infty^{\tau_{mod}\text{-reg}} X$.

Note that $\Lambda(\Gamma)$ is compact, as is its type projection to σ_{mod} . A quantitative version of uniform regularity is given by:

Definition 5.2 (Θ -regular). Let $\Theta \subset \text{ost}(\tau_{mod})$ be compact. The subgroup Γ is called *Θ -regular* if its visual limit set consists only of ideal points of type Θ , $\Lambda(\Gamma) \subset \theta^{-1}(\Theta) \subset \partial_\infty^{\tau_{mod}\text{-reg}} X$.

These notions apply in the same way to divergent sequences (x_n) in X and (g_n) in G , the latter by looking at the accumulation set in $\partial_\infty X$ of an associated orbit sequence $(g_n x)$ for a(ny) base point x .

Now we define (non-uniform) weak regularity itself. We denote by $\partial \text{ost}(\tau_{mod}) = \sigma_{mod} - \text{ost}(\tau_{mod})$ the set of τ_{mod} -singular types.

Definition 5.3 (Weakly regular sequence). (i) A sequence $\delta_n \rightarrow \infty$ in $\Delta = V_{mod}$ is τ_{mod} -regular if

$$d(\delta_n, V(0, \sigma_{mod} - \text{ost}(\tau_{mod}))) \rightarrow +\infty. \tag{5.4}$$

(ii) A sequence $x_n \rightarrow \infty$ in X is τ_{mod} -regular if for some (any) base point x the sequence of Δ -valued lengths $d_\Delta(x, x_n)$ in Δ has this property.

(iii) A sequence $g_n \rightarrow \infty$ in G is τ_{mod} -regular if some (any) orbit $(g_n x)$ in X has this property.

Remark 5.5. (i) The independence of the base point and the orbit in parts (ii) and (iii) of the definition is due to the triangle inequality $|d_\Delta(x, y) - d_\Delta(x', y')| \leq d(x, x') + d(y, y')$.

(ii) *Uniform* τ_{mod} -regularity is equivalent to *linear* (with respect to $|\delta_n|$) divergence in (5.4).

(iii) If the sequence (x_n) is τ_{mod} -regular, then every sequence (x'_n) uniformly close to it, $\sup_n d(x_n, x'_n) < +\infty$, is also τ_{mod} -regular, again by the triangle inequality. Similarly, if the sequence (g_n) in G is τ_{mod} -regular, then for all bounded sequences (b_n) and (b'_n) in G , the sequence $(b_n g_n b'_n)$ is also τ_{mod} -regular.

(v) (Uniform) τ_{mod} -regularity implies (uniform) τ'_{mod} -regularity for all face types $\tau'_{mod} \subset \tau_{mod}$, because $\text{ost}(\tau_{mod}) \subset \text{ost}(\tau'_{mod})$.

(vi) Every diverging sequence has a weakly regular subsequence, i.e. a subsequence which is τ_{mod} -regular for some face type τ_{mod} .

Definition 5.6 (Weakly regular subgroup). A subgroup $\Gamma \subset G$ is τ_{mod} -regular if all sequences $\gamma_n \rightarrow \infty$ in Γ have this property. When we do not want to specify τ_{mod} , we refer to Γ simply as *weakly regular*.

Remark 5.7. (i) The definition of τ_{mod} -regularity for *sequences* makes sense also if τ_{mod} is not ι -invariant. Then a sequence (g_n) in G is (uniformly) τ_{mod} -regular if and only if the sequence (g_n^{-1}) of inverses is (uniformly) $\iota\tau_{mod}$ -regular, cf. the symmetry property (2.2) for Δ -lengths. When defining τ_{mod} -regularity for *subgroups*, it is therefore natural to require the ι -invariance of the simplex τ_{mod} , and this is why we impose this condition in the entire paper.

(ii) A discrete subgroup $\Gamma \subset G$ needs not be τ_{mod} -regular (for any τ_{mod}) even if all its nontrivial elements are regular (transvections). This can happen e.g. for free abelian subgroups of rank ≥ 2 .

Remark 5.8 (Relation to visual compactifications for Finsler metrics). We recall that a sequence $x_n \rightarrow \infty$ converges to an ideal point in the visual compactification if and only if the normalized distance functions $d(\cdot, x_n) - d(p, x_n)$ converge (locally uniformly), where p is some base point. Ideal boundary points can thus be identified with normalized Busemann functions. The same construction can be carried out for G -invariant *Finsler* metrics on X and one obtains modified visual compactifications. To a face type τ_{mod} we can associate a Finsler metric as follows. Fix a ι -invariant unit vector $v \in \Delta$ pointing to an interior point of τ_{mod} (e.g. its center), and define $d_v(x, x') := \langle d_\Delta(x, x'), v \rangle$. In the visual boundary with respect to this Finsler metric there is a unique G -orbit which is a copy of $\text{Flag}(\tau_{mod})$; its points correspond to collapsed open stars around simplices of type τ_{mod} in $\partial_\infty X$. (The union $X \cup \text{Flag}(\tau_{mod})$ is the natural τ_{mod} -bordification of X .) The relation with τ_{mod} -regularity is as follows: A subgroup Γ is τ_{mod} -regular if and only if its visual limit set with respect to the modified compactification of X is contained in the G -orbit $\text{Flag}(\tau_{mod})$.

5.2 Contraction-expansion dynamics at infinity

In this section, we will describe how the weak regularity of sequences in G can be read off their dynamics at infinity. Roughly speaking, on appropriate flag manifolds, certain almost full subsets are contracted, asymptotically, almost to points. Dually, small balls are expanded to almost full subsets. This “contraction-expansion dynamics” is a generalization of convergence dynamics in rank one to arbitrary rank.

5.2.1 Contraction and expansion

We now formulate the contraction and expansion properties for sequences in G and show that they are satisfied by weakly regular sequences. We first state and discuss contraction.

Definition 5.9 (Contraction). Let (g_n) be a sequence in G . We call a sequence of subsets $U_n \subset \text{Flag}(\tau_{mod})$ a *contraction sequence* for (g_n) if it satisfies the following properties:

(i) It is *exhaustive* in the sense that there exist a bounded sequence (b_n) in G and a simplex τ of type τ_{mod} such that $b_n U_n \rightarrow C(\tau)$, meaning that every compact subset of the open Schubert stratum $C(\tau)$ is contained in $b_n U_n$ for n sufficiently large.

(ii) The image subsets $g_n U_n$ *shrink* in the sense that there exists a bounded sequence (b_n) in G such that $b_n g_n U_n$ Hausdorff converges to a point, equivalently, if $\text{diam}(g_n U_n) \rightarrow 0$ with respect to a Riemannian background metric on $\text{Flag}(\tau_{mod})$.

We call the sequence (g_n) *contracting* on $\text{Flag}(\tau_{mod})$ if it admits a contraction sequence.

Note that open Schubert strata are dense open subsets of full volume with respect to any auxiliary smooth probability measure on $\text{Flag}(\tau_{mod})$. Hence the subsets in a (measurable) exhausting sequence have asymptotically full volume.

Property (i) in the definition means that the subsets U_n asymptotically fill out the sequence of moving open Schubert strata $b_n^{-1} C(\tau) = C(b_n^{-1} \tau)$, and property (ii) means that the images $g_n U_n$ asymptotically concentrate to points which are also allowed to move.

Note that if the sequence (g_n) in G is contracting, then for all bounded sequences (b_n) and (b'_n) in G , the sequence $(b_n g_n b'_n)$ is also contracting.

We will say that a contraction sequence (U_n) is *opposite* to a sequence (τ_n) in $\text{Flag}(\tau_{mod})$ if $U_n \subset C(\tau_n)$ for large n . Note that in the definition the sequence $(U_n \cap C(b_n^{-1} \tau))$ is still exhaustive, and hence a contraction sequence for (g_n) opposite to the sequence $(b_n^{-1} \tau)$.

The contraction property can be reformulated in terms of concentration of measures, which shows that it essentially agrees with other notions of contraction (on flag manifolds) used in the literature, cf. [GoM, §3]: If a sequence (g_n) is contracting in the above sense, then there exists a bounded sequence (b_n) such that the sequence of measures $(b_n g_n)_* \mu$ converges to a Dirac mass for any smooth probability measure μ on $\text{Flag}(\tau_{mod})$. Moreover, one can also prove the converse. Note that we do not require the measures $g_n_* \mu$ themselves to converge, but allow them to concentrate around any sequence of moving points. Since flag manifolds are compact, one can always achieve by passing to a subsequence that also the measures $g_n_* \mu$ converge.

Remark 5.10 (Proximal). Related to the notion of contraction is the notion of *proximality*, see e.g. [Ab]. Say that an element $g \in G$ acts as a *proximal transformation* on $\text{Flag}(\tau_{mod})$ if the sequence $(g^n)_{n \in \mathbb{N}}$ converges to a point $\tau_+ \in \text{Flag}(\tau_{mod})$ locally uniformly on an open Schubert stratum $C(\tau_-) \subset \text{Flag}(\tau_{mod})$, where τ_- is a simplex antipodal to τ_+ . We will refer to τ_+ as the *attractive* fixed point of g . (Note that it is necessarily fixed by g). The sequence (g^n) is then contracting on $\text{Flag}(\tau_{mod})$. Note however that vice versa sequences, which are contracting on $\text{Flag}(\tau_{mod})$, need not contain proximal elements. For instance, in the rank one case all divergent

sequences in G are contracting due to convergence dynamics.

The expansion property is dual to contraction:

Definition 5.11 (Expansion). Let (g_n) be a sequence in G . We call a sequence of subsets $V_n \subset \text{Flag}(\tau_{mod})$ an *expansion sequence* for (g_n) if it satisfies the following properties:

- (i) It shrinks, $\text{diam}(V_n) \rightarrow 0$.
- (ii) The sequence of image subsets $g_n V_n$ is exhaustive.

We call the sequence (g_n) *expanding* on $\text{Flag}(\tau_{mod})$ if it admits an expansion sequence.

The duality means that (U_n) is a contraction sequence for (g_n) if and only if $(g_n U_n)$ is an expansion sequence for (g_n^{-1}) .

5.2.2 Strong asymptoticity of Weyl cones

Before proceeding, we need to prove a fact from the geometry of symmetric spaces.

Let $\tau \in \partial_\infty X$ be a simplex of type τ_{mod} . For a point $x \in X$ we have on the open Schubert stratum $C(\tau) \subset \text{Flag}(\tau_{mod})$ the function

$$\tau' \mapsto d(x, P(\tau, \tau')).$$

It is continuous and proper. (This follows from the fact that $C(\tau)$ and X are homogeneous spaces for the parabolic subgroup P_τ .) It has a unique minimum zero in the chamber $\hat{\tau}_x$ which is opposite to τ with respect to x .

We define the following open subsets of $C(\tau)$ which can be regarded as “shadows” of balls with respect to τ . For $x \in X$ and $r > 0$, we put

$$U_{\tau,x,r} := \{\tau' \in C(\tau) \mid d(x, P(\tau, \tau')) < r\}.$$

Then the subsets $U_{\tau,x,r}$ for fixed τ and x form a neighborhood basis of $\hat{\tau}_x$.

The next fact expresses the uniform strong asymptoticity of asymptotic Weyl cones.

Lemma 5.12. *For $r, R > 0$ exists $d = d(r, R) > 0$ such that:*

If $y \in V(x, \text{st}(\tau))$ with $d(y, \partial V(x, \text{st}(\tau))) \geq d(R, r)$, then $U_{\tau,x,R} \subset U_{\tau,y,r}$.

Proof. If $U_{\tau,x,R} \not\subset U_{\tau,y,r}$ then there exists $x' \in B(x, r)$ such that $d(y, V(x', \text{st}(\tau))) \geq r$. Thus, if the assertion is wrong, there exist a sequence $x_n \rightarrow x_\infty$ in $B(x, r)$ and a sequence $y_n \rightarrow \infty$ in $V(x, \text{st}(\tau))$ such that $d(y_n, \partial V(x, \text{st}(\tau))) \rightarrow +\infty$ and $d(y_n, V(x_n, \text{st}(\tau))) \geq r$.

Let $\rho : [0, +\infty) \rightarrow V(x, \text{st}(\tau))$ be a geodesic ray with initial point x and asymptotic to an interior point of τ . Then the sequence (y_n) eventually enters every Weyl sector $V(\rho(t), \text{st}(\tau))$. Since the distance function $d(\cdot, V(x_n, \text{st}(\tau)))$ is convex and bounded, and hence non-increasing along rays asymptotic to $\text{st}(\tau)$, we have that

$$R \geq d(x, V(x_n, \text{st}(\tau))) \geq d(\rho(t), V(x_n, \text{st}(\tau))) \geq d(y_n, V(x_n, \text{st}(\tau))) \geq r$$

for n large. It follows that

$$R \geq d(\rho(t), V(x_\infty, \text{st}(\tau))) \geq r$$

for all t . However, if ρ is asymptotic to $V(x_\infty, \text{st}(\tau))$, then it is strongly asymptotic, a contradiction. \square

5.2.3 Regularity implies contraction-expansion

We are now ready to show that weakly regular sequences in G are contracting-expanding on suitable flag manifolds.

The following flexible and base point independent notion of radial projection to infinity will be useful for describing contraction and expansion sequences.

Definition 5.13 (Shadows at infinity). A *shadow sequence* of a sequence (x_n) in X is a sequence (τ_n) of simplices in $\text{Flag}(\tau_{\text{mod}})$ such that

$$\sup_n d(x_n, V(x, \text{st}(\tau_n))) < +\infty$$

for some (any) base point x . A shadow sequence of a sequence (g_n) in G is a sequence of shadows for an orbit sequence $(g_n x)$ for some (any) base point x .

Proposition 5.14. τ_{mod} -regular sequences in G are contracting and expanding on $\text{Flag}(\tau_{\text{mod}})$. More precisely, let (g_n) be a τ_{mod} -regular sequence in G . Then for a shadow sequence (τ_n^-) of (g_n^{-1}) there exists

- (i) a contraction sequence (U_n) for (g_n) opposite to (τ_n^-) , i.e. $U_n \subset C(\tau_n^-)$.
- (ii) an expansion sequence (V_n) for (g_n) containing (τ_n^-) , i.e. $\tau_n^- \in V_n$.

Proof. (i) We fix a base point x and denote by $g_n^{-1}x_n$ the nearest point projection of $g_n^{-1}x$ to $V(x, \text{st}(\tau_n^-))$. Then the sequence (x_n) is bounded. Due to τ_{mod} -regularity, we have that

$$d(g_n^{-1}x_n, \partial V(x, \text{st}(\tau_n^-))) \rightarrow +\infty.$$

Lemma 5.12 yields that for any $r, R > 0$ the inclusion

$$U_{\tau_n^-, x, R} \subset U_{\tau_n^-, g_n^{-1}x_n, r}$$

holds for large n . Therefore there exist sequences of positive numbers $R_n \rightarrow +\infty$ and $r_n \rightarrow 0$ such that

$$g_n U_{\tau_n^-, x, R_n} \subset U_{g_n \tau_n^-, x_n, r_n}$$

for large n . The sequence $(U_{\tau_n^-, x, R_n})$ is exhaustive, and the sequence $(U_{g_n \tau_n^-, x_n, r_n})$ shrinks because (x_n) is bounded. Hence $(U_{\tau_n^-, x, R_n})$ is a contraction sequence for (g_n) , and $U_{\tau_n^-, x, R_n} \subset C(\tau_n^-)$.

(ii) Let $g_n^{-1}\tau_n^+$ be the simplices opposite to τ_n^- with respect to x . Similarly, Lemma 5.12 implies that

$$U_{g_n^{-1}\tau_n^+, g_n^{-1}x_n, R_n} \subset U_{g_n^{-1}\tau_n^+, x, r_n} \ni \tau_n^-$$

for suitable sequences $R_n \rightarrow +\infty$ and $r_n \rightarrow 0$. The sequence $(U_{\tau_n^+, x_n, R_n})$ is exhaustive because (x_n) is bounded, and it follows that $(U_{g_n^{-1}\tau_n^+, x, r_n})$ is an expansion sequence for (g_n) . \square

The proposition has several useful consequences.

Firstly, the various shadow sequences of a weakly regular sequence approach each other. We will use this below to define flag convergence.

Lemma 5.15 (Asymptotic uniqueness of shadows). *For a τ_{mod} -regular sequence (g_n) in G any two shadow sequences (τ_n) and (τ'_n) asymptotically coincide, i.e. $d(\tau_n, \tau'_n) \rightarrow 0$.*

Proof. By Proposition 5.14 (Part (ii)), there exist expansion sequences (V_n) and (V'_n) for (g_n^{-1}) such that $\tau_n \in V_n$ and $\tau'_n \in V'_n$. The assertion follows from the fact that any two expansion sequences asymptotically coincide, i.e. $\text{diam}(V_n \cup V'_n) \rightarrow 0$.

To see the latter, note that $(g_n^{-1}V_n)$ and $(g_n^{-1}V'_n)$ are contraction sequences for (g_n) . In particular, they are exhaustive and therefore asymptotically intersect by volume reasons, that is $g_n^{-1}V_n \cap g_n^{-1}V'_n \neq \emptyset$ for large n . So, $V_n \cap V'_n \neq \emptyset$ for large n , and hence $\text{diam}(V_n \cup V'_n) \rightarrow 0$, as claimed. \square

Secondly, shadow sequences asymptotically agree with the values on contraction subsets:

Lemma 5.16. *Let (g_n) be a τ_{mod} -regular sequence in G . Then for any contraction sequence (U_n) and any shadow sequence (τ_n) , the subsets $g_n U_n \cup \{\tau_n\}$ shrink, $\text{diam}(g_n U_n \cup \{\tau_n\}) \rightarrow 0$.*

Proof. Note that $(g_n U_n)$ is an expansion sequence for (g_n^{-1}) . According to Proposition 5.14 (Part (ii)) applied to (g_n^{-1}) there exists another expansion sequence (V_n^-) for (g_n^{-1}) such that $\tau_n \in V_n^-$. The assertion follows from the asymptotic uniqueness of expansion sequences, compare the proof of Lemma 5.15, which yields that $\text{diam}(g_n U_n \cup V_n^-) \rightarrow 0$. \square

Remark 5.17. The last result relates the asymptotics of orbits in X and the dynamics at infinity. One can promote it to showing that τ_{mod} -regular sequences in G have contraction-expansion dynamics on the bordification $X \cup \text{Flag}(\tau_{mod})$.

5.2.4 Contraction implies regularity

We consider now sequences (g_n) in G which are contracting on $\text{Flag}(\tau_{mod})$, and show that they are τ_{mod} -regular.

The key step is a converse to Proposition 5.14 (i), essentially saying that sequences opposite to contraction sequences for (g_n) asymptotically coincide with shadow sequences for (g_n^{-1}) :

Lemma 5.18. *Let (U_n) be a contraction sequence for (g_n) , and let (τ_n^-) be a shadow sequence of (g_n^{-1}) . Suppose that (τ_n) is a sequence in $\text{Flag}(\tau_{mod})$ such that $(U_n \cap C(\tau_n))$ is still exhaustive. Then $d(\tau_n, \tau_n^-) \rightarrow 0$.*

Proof. By passing to a subsequence, we may assume convergence $\tau_n^- \rightarrow \tau_-$ and $\tau_n \rightarrow \tau$. It suffices to show that then $\tau_- = \tau$.

We look at the dynamics of (g_n) on the space of maximal flats. Recall that a sequence of maximal flats $F_n \subset X$ is bounded if $d(x, F_n)$ is bounded for a base point $x \in X$.

Suppose that (F_n) is a bounded sequence of maximal flats, such that the sequence $(g_n F_n)$ of image flats is also bounded. We will see that its position relative to τ is restricted. Consider a maximal flat F which is the limit of a subsequence of (F_n) .

Sublemma 5.19. *The apartment $\partial_\infty F \subset \partial_\infty X$ contains exactly one simplex opposite to τ .*

Proof. In a spherical building, every point has an antipode in every apartment. Hence, $\partial_\infty F$ contains at least one simplex $\hat{\tau}$ opposite to τ . Suppose that it contains another simplex $\hat{\tau}'$ opposite to τ . After passing to a subsequence, we may assume that $F_n \rightarrow F$. Let $\hat{\tau}_n, \hat{\tau}'_n \subset \partial_\infty F_n$ be approximating simplices, $\hat{\tau}_n \rightarrow \hat{\tau}$ and $\hat{\tau}'_n \rightarrow \hat{\tau}'$. Since $(g_n F_n)$ is bounded, after passing to a subsequence, the sequences $(g_n \hat{\tau}_n)$ and $(g_n \hat{\tau}'_n)$ converge to *distinct* limit simplices. On the other hand, in view of $\hat{\tau}, \hat{\tau}' \in C(\tau)$, we have that $\hat{\tau}_n, \hat{\tau}'_n \in U_n$ for large n . Since $(g_n U_n)$ shrinks, it follows that $d(g_n \hat{\tau}_n, g_n \hat{\tau}'_n) \rightarrow 0$, a contradiction. \square

We need the following general fact from spherical building geometry.

Sublemma 5.20. *Let ξ be a point in a spherical building B and let $a \subset B$ be an apartment. If ξ has only one antipode in a , then $\xi \in a$.*

Proof. Suppose that $\xi \notin a$ and let $\hat{\xi} \in a$ be an antipode of ξ . (It always exists.) We choose a "generic" segment $\xi\hat{\xi}$ of length π tangent to a at $\hat{\xi}$ as follows. The suspension $B(\xi, \hat{\xi}) \subset B$ contains an apartment a' with the same unit tangent sphere at $\hat{\xi}$, $\Sigma_{\hat{\xi}} a' = \Sigma_{\hat{\xi}} a$. Inside a' there exists a segment $\xi\hat{\xi}$ whose interior does not meet simplices of codimension ≥ 2 . Hence $\xi\hat{\xi}$ leaves a at an interior point $\eta \neq \xi, \hat{\xi}$ of a panel $\pi \subset a$, i.e. $a \cap \xi\hat{\xi} = \eta\hat{\xi}$ and $\pi \cap \xi\hat{\xi} = \eta$, and $\eta\xi$ initially lies in a chamber adjacent to π but not contained in a . Let $s \subset a$ be the wall (codimension one singular sphere) containing π . By reflecting $\hat{\xi}$ at s , one obtains a second antipode for ξ in a , contradiction. \square

Returning to the proof of the lemma, it follows that $\tau \subset \partial_\infty F$.

Sequences (F_n) of maximal flats satisfying our assumptions are obtained as follows. Since (τ_n^-) is a shadow of (g_n^{-1}) in $\text{Flag}(\tau_{mod})$, there exist chambers $\sigma_n^- \supset \tau_n^-$ such that (σ_n^-) is a shadow of (g_n^{-1}) in $\partial_F X$, that is

$$\sup_n d(g_n^{-1}x, V(x, \sigma_n^-)) < +\infty$$

for a(ny) point $x \in X$. Then the flats F_n extending the euclidean Weyl chambers $V(x, \sigma_n^-)$ have the property that both sequences (F_n) and $(g_n F_n)$ are bounded.

A subsequence of (F_n) converges iff the corresponding subsequence of (σ_n^-) of chambers converges, and the limit flat contains the Weyl sector $V(x, \tau_-)$. In particular, it is itself contained in the parallel set $P(\tau_-, \hat{\tau}_-)$ for the simplex $\hat{\tau}_-$ opposite to τ_- with respect to x . It follows from the above that $\tau \subset \partial_\infty P(\tau_-, \hat{\tau}_-)$. Since the point x is arbitrary, $\hat{\tau}_-$ can be any simplex opposite

to τ_- , and we obtain that

$$\tau \subset \bigcap_{\hat{\tau}_- \in C(\tau_-)} \partial_\infty P(\tau_-, \hat{\tau}_-) = \text{st}(\tau_-),$$

which implies that $\tau = \tau_-$. □

Lemma 5.18 has various implications of asymptotic uniqueness. Firstly, it yields the asymptotic uniqueness of shadows of the inverse of a contracting sequence. From this, in turn, follows regularity and we obtain the converse of Proposition 5.14:

Proposition 5.21 (Contraction implies regularity). *Sequences in G , which are contracting on $\text{Flag}(\tau_{mod})$, are τ_{mod} -regular.*

Proof. Suppose that the sequence (g_n) in G is contracting on $\text{Flag}(\tau_{mod})$ but not τ_{mod} -regular. Then the sequence (g_n^{-1}) is not τ_{mod} -regular either and, after passing to a subsequence, we may assume that there exists a converging sequence $\pi_n^- \rightarrow \pi_-$ of panels (codimension one simplices) of fixed face type $\theta(\pi_n^-) \not\supset \tau_{mod}$ such that

$$\sup_n d(g_n^{-1}x, V(x, \pi_n^-)) < +\infty \tag{5.22}$$

for a(ny) point $x \in X$.

Let τ_n^- be simplices of type τ_{mod} such that τ_n^- and π_n^- are faces of the same chamber. (This is equivalent to $\tau_n^- \subset \partial \text{st}(\pi_n^-)$, respectively, to $\pi_n^- \subset \partial \text{st}(\tau_n^-)$.) Note that $\tau_n^- \not\supset \pi_n^-$ because $\theta(\pi_n^-) \not\supset \tau_{mod}$, and hence the τ_n^- are non-unique. Any such sequence (τ_n^-) is a shadow of (g_n^{-1}) in $\text{Flag}(\tau_{mod})$. These sequences (τ_n^-) can accumulate at any simplex τ_- of type τ_{mod} contained in $\partial \text{st}(\pi_-)$. Again, since $\theta(\pi_-) \not\supset \tau_{mod}$, there are several such simplices τ_- . In particular, shadow sequences of (g_n^{-1}) are not asymptotically unique. This contradicts Lemma 5.18. □

Combining Propositions 5.14 and 5.21, we obtain a characterization of weak regularity in terms of dynamics at infinity:

Theorem 5.23 (Contraction characterizes regularity). *A sequence in G is τ_{mod} -regular if and only if it is contracting on $\text{Flag}(\tau_{mod})$.*

Secondly, an immediate consequence of Lemma 5.18 is the following asymptotic uniqueness statement for contraction sequences complementing the asymptotic uniqueness of expansion and shadow sequences, cf. Lemma 5.15:

Lemma 5.24 (Asymptotic uniqueness of contraction sequences). *Suppose that (U_n) and (U'_n) are contraction sequences for (g_n) , and that (τ_n) and (τ'_n) are sequences in $\text{Flag}(\tau_{mod})$ such that $(U_n \cap C(\tau_n))$ and $(U'_n \cap C(\tau'_n))$ are still exhaustive. Then $d(\tau_n, \tau'_n) \rightarrow 0$.*

Another consequence of Lemma 5.18 and our earlier discussion of the contraction-expansion dynamics of weakly regular sequences is:

Lemma 5.25 (Contraction and expansion sequences are asymptotically opposite).

Let (g_n) be a τ_{mod} -regular sequence in G . Suppose that (U_n) is a contraction and (V_n) an expansion sequence for (g_n) . Furthermore, let (τ_n) be a sequence on $\text{Flag}(\tau_{mod})$ such that $(U_n \cap C(\tau_n))$ is still exhaustive. Then $V_n \cup \{\tau_n\}$ shrinks, $\text{diam}(V_n \cup \{\tau_n\}) \rightarrow 0$.

Proof. Combine Lemma 5.18 with Proposition 5.14 and the proof of Lemma 5.15. □

5.3 Flag convergence

The asymptotic uniqueness of shadow sequences, see Lemma 5.15, leads to a notion of convergence at infinity for weakly regular sequences with limits in the appropriate flag manifolds. Namely, we can define convergence as the convergence of their shadows:

Definition 5.26 (Flag convergence). A τ_{mod} -regular sequence in X or G *flag converges* to a simplex $\tau \in \text{Flag}(\tau_{mod})$, if one (any) of its shadow sequences in $\text{Flag}(\tau_{mod})$ converges to τ .

We denote the flag convergence of a sequence (x_n) or (g_n) by $x_n \xrightarrow{f} \tau$, respectively, $g_n \xrightarrow{f} \tau$. If we want to refer to the face type τ_{mod} , we will sometimes also say that the sequence τ_{mod} -converges or speak of flag convergence of type τ_{mod} .

Note that a τ_{mod} -regular sequence always has a τ_{mod} -converging subsequence due to the compactness of $\text{Flag}(\tau_{mod})$.

Remark 5.27. (i) Flag convergence of type τ_{mod} captures convergence “transversely to the stars of the simplices of type τ_{mod} ”. It is related to the “usual” convergence at infinity with respect to the visual compactification $\bar{X} = X \cup \partial_\infty X$ as follows. If a τ_{mod} -regular sequence flag converges to $\tau \in \text{Flag}(\tau_{mod})$, then it accumulates in the visual compactification at $\text{st}(\tau) \subset \partial_\infty X$; however, the converse is in general not true. For *uniformly* τ_{mod} -regular sequences, one has equivalence: They flag converge to τ if and only if they accumulate in \bar{X} at $\text{ost}(\tau)$.

(ii) Flag convergence of type τ_{mod} can be understood as convergence at infinity with respect to a *modified* visual compactification, namely as convergence in the τ_{mod} -bordification $X \cup \text{Flag}(\tau_{mod})$ of X , compare Remark 5.8.

(iii) τ_{mod} -Convergence implies τ'_{mod} -convergence for smaller face types $\tau'_{mod} \subset \tau_{mod}$, and the limits correspond under the natural forgetful projection $\text{Flag}(\tau_{mod}) \rightarrow \text{Flag}(\tau'_{mod})$.

Flag convergence of weakly regular sequences in G can be characterized in different ways in terms of the dynamics at infinity.

Firstly, one can use the close relation between the asymptotics of orbits in X and the dynamics on flag manifolds, as expressed by Lemma 5.16. Since shadow sequences asymptotically agree with the values on contraction subsets, one has the equivalence: A τ_{mod} -regular sequence (g_n) in G flag converges to $\tau \in \text{Flag}(\tau_{mod})$ if and only if for the image sequences $(g_n U_n)$ of its contraction sequences (U_n) in $\text{Flag}(\tau_{mod})$ shrink to τ , $g_n U_n \rightarrow \tau$.

Secondly, one can read off flag convergence from the dynamics of the sequence of inverses:

Lemma 5.28. *For a τ_{mod} -regular sequence (g_n) in G the following two conditions are equivalent:*

(i) $g_n \xrightarrow{f} \tau \in \text{Flag}(\tau_{mod})$.

(ii) (g_n^{-1}) admits a contraction sequence (U_n^-) in $\text{Flag}(\tau_{mod})$ opposite to τ , i.e. $U_n^- \subset C(\tau)$.

Proof. The direction (i) \Rightarrow (ii) follows from our construction of contraction sequences: Let (τ_n) be a shadow of (g_n) in $\text{Flag}(\tau_{mod})$. Then $\tau_n \rightarrow \tau$, and we apply Proposition 5.14(i) to (g_n^{-1}) .

The reverse direction follows from the asymptotic uniqueness of contraction sequences: Namely, invoking Proposition 5.14(i) again, there exists another contraction sequence $(U_n'^-)$ for (g_n^{-1}) which is opposite to a shadow (τ_n') of (g_n) . Lemma 5.24 then implies that $\tau_n' \rightarrow \tau$. \square

Our next observation concerns the relation between flag convergence of sequences in G and their convergence as sequences of maps (homeomorphisms) of flag manifolds.

For a τ_{mod} -converging sequence $g_n \xrightarrow{f} \tau$ in G , one can in general not conclude *pointwise* convergence of (g_n) to τ anywhere on $\text{Flag}(\tau_{mod})$. The reason being that in general no nested (monotonic) contraction sequence (U_n) exists because there is no control on the sequence of open Schubert strata which it approximates; if (U_n) is opposite to a sequence (τ_n^-) in $\text{Flag}(\tau_{mod})$, $U_n \subset C(\tau_n^-)$, then (τ_n^-) can be arbitrary.

However, after passing to a subsequence so that also (g_n^{-1}) flag converges, one obtains for (g_n) and (g_n^{-1}) *locally uniform* convergence on open Schubert strata:

Proposition 5.29 (Attraction-repulsion). *For a τ_{mod} -regular sequence (g_n) in G , we have flag convergence $g_n^{\pm 1} \xrightarrow{f} \tau_{\pm} \in \text{Flag}(\tau_{mod})$ if and only if*

$$g_n^{\pm 1} \rightarrow \tau_{\pm}$$

locally uniformly on $C(\tau_{\mp})$ as homeomorphisms of $\text{Flag}(\tau_{mod})$.

Proof. Suppose that $g_n^{\pm 1} \xrightarrow{f} \tau_{\pm}$. Then there exist contraction sequences (U_n^{\pm}) for $(g_n^{\pm 1})$ in $\text{Flag}(\tau_{mod})$ opposite to τ_{\mp} , cf. Lemma 5.28. Moreover, $g_n^{\pm 1} U_n^{\pm} \rightarrow \tau_{\pm}$, cf. Lemma 5.16 or our remark above. Together, this means that $g_n^{\pm 1} \rightarrow \tau_{\pm}$ locally uniformly on $C(\tau_{\mp})$.

Conversely, if $g_n^{\pm 1} \rightarrow \tau_{\pm}$ locally uniformly on $C(\tau_{\mp})$, then there exist contraction sequences (U_n^{\pm}) for $(g_n^{\pm 1})$ such that $g_n^{\pm 1} U_n^{\pm} \rightarrow \tau_{\pm}$, and Lemma 5.16 implies that $g_n^{\pm 1} \xrightarrow{f} \tau_{\pm}$. \square

Remark 5.30. There is no restriction on the relative position of the pair of simplices τ_{\pm} . They may even agree.

Example 5.31. Fix a maximal flat $F \subset X$ and a simplex $\tau \subset \partial_{\infty} F$. Let (ϑ_n) be a sequence of transvections along F such that the expansion factors $\epsilon(\vartheta_n^{-1}, \tau)$ for the action of ϑ_n on the flag manifold $\text{Flag}(\theta(\tau)) = G\tau$ satisfy

$$\lim_{n \rightarrow \infty} \epsilon(\vartheta_n^{-1}, \tau) = +\infty.$$

In view of Theorem 2.54, this is equivalent to $\vartheta_n x \in V(x, \text{st}(\tau) \cap \partial_\infty F)$ for large n , with $x \in F$ fixed, and to the sequence (ϑ_n) being τ_{mod} -regular, where $\tau_{mod} = \theta(\tau)$. Then $\vartheta_n \xrightarrow{f} \tau$, because the constant sequence (τ) is a shadow of (ϑ_n) in $\text{Flag}(\tau_{mod})$.

5.4 Flag limit sets

We now consider discrete subgroups $\Gamma \subset G$.

We recall that the *visual limit set* $\Lambda(\Gamma) \subset \partial_\infty X$ is defined as the set of accumulation points of an(y) orbit $\Gamma x \subset X$ in the visual compactification $\bar{X} = X \cup \partial_\infty X$, i.e. $\Lambda(\Gamma) = \overline{\Gamma x} \cap \partial_\infty X$. The notion of flag convergence allows to associate to Γ in an analogous way visual limit sets in the flag manifolds associated to G .

Definition 5.32 (Flag limit set). Let $\Gamma \subset G$ be a discrete subgroup. We define its *flag limit set* of type τ_{mod} or *τ_{mod} -limit set* $\Lambda_{\tau_{mod}}(\Gamma) \subset \text{Flag}(\tau_{mod})$ as the set of all limit simplices of τ_{mod} -converging sequences in Γ . We call $\Lambda_{\sigma_{mod}}(\Gamma) \subset \partial_F X$ the *chamber limit set* of Γ .

In other words, $\Lambda_{\tau_{mod}}(\Gamma)$ is the set of accumulation points $\overline{\Gamma x} \cap \text{Flag}(\tau_{mod})$ of an(y) orbit $\Gamma x \subset X$ in the τ_{mod} -bordification $X \cup \text{Flag}(\tau_{mod})$.

Remark 5.33. (i) $\Lambda_{\tau_{mod}}(\Gamma)$ is compact and Γ -invariant.

(ii) $\Lambda_{\tau_{mod}}(\Gamma)$ is nonempty if and only if Γ contains a τ_{mod} -regular sequence $\gamma_n \rightarrow \infty$, i.e. if part of the Γ -action on $\text{Flag}(\tau_{mod})$ is contracting. In particular, $\Lambda_{\tau_{mod}}(\Gamma)$ is nonempty if Γ is an infinite τ_{mod} -regular subgroup.

(iii) If Γ is uniformly τ_{mod} -regular, then $\Lambda_{\tau_{mod}}(\Gamma)$ is the image of $\Lambda(\Gamma)$ under the natural projection $\partial_\infty^{\tau_{mod}\text{-reg}} X \rightarrow \text{Flag}(\tau_{mod})$.

(iv) If $\tau'_{mod} \subset \tau_{mod}$, then $\Lambda_{\tau_{mod}}(\Gamma)$ maps onto $\Lambda_{\tau'_{mod}}(\Gamma)$ via the natural forgetful projection $\text{Flag}(\tau_{mod}) \rightarrow \text{Flag}(\tau'_{mod})$.

For sufficiently generic subgroups the limit sets are perfect and the groups act on them minimally:

Proposition 5.34 (Minimality and perfectness). *Suppose that $\Lambda_{\tau_{mod}}(\Gamma) \neq \emptyset$ and that for all $\lambda \in \Lambda_{\tau_{mod}}(\Gamma)$ and $\tau \in \text{Flag}(\tau_{mod})$ we have $\Gamma\tau \cap C(\lambda) \neq \emptyset$. Then $\Lambda_{\tau_{mod}}(\Gamma)$ is the unique minimal nonempty Γ -invariant compact subset of $\text{Flag}(\tau_{mod})$.*

If in addition $\Lambda_{\tau_{mod}}(\Gamma)$ is infinite, then it is perfect.

Proof. Let $\lambda_+ \in \Lambda_{\tau_{mod}}(\Gamma)$. For minimality, we must show that λ_+ is contained in the closure of every Γ -orbit $\Gamma\tau$ in $\text{Flag}(\tau_{mod})$. By definition of the limit set, there exists a τ_{mod} -regular sequence (γ_n) in Γ such that $\gamma_n^{\pm 1} \xrightarrow{f} \lambda_\pm$ with some $\lambda_- \in \Lambda_{\tau_{mod}}(\Gamma)$, and hence $\gamma_n^{\pm 1} \rightarrow \lambda_\pm$ locally uniformly on $C(\lambda_\mp)$. By assumption, we have $\Gamma\tau \cap C(\lambda_-) \neq \emptyset$. It follows that $\lambda_+ \in \overline{\Gamma\tau}$.

It remains to show perfectness. Suppose that $\Lambda_{\tau_{mod}}(\Gamma)$ contains isolated points. The non-isolated limit points (simplices) form a closed subset which, by minimality, must be empty.

Hence, all limit points are isolated and, by compactness, the limit set is finite. \square

Remark 5.35. (i) The condition that every Γ -orbit on $\text{Flag}(\tau_{mod})$ intersects every open Schubert stratum is satisfied by *Zariski dense* subgroups Γ . Indeed, the action $G \curvearrowright \text{Flag}(\tau_{mod})$ is an algebraic action of a semisimple algebraic group on a projective variety. In this setting, Zariski dense subgroups of G have Zariski dense orbits (because the Zariski closure of a subgroup preserves the Zariski closure of any of its orbits). So, no orbit can avoid an open Schubert stratum because its complement, a Schubert cycle, is a subvariety. If $\Lambda_{\tau_{mod}}(\Gamma)$ is nonempty and finite, then Γ is virtually contained in a parabolic subgroup and can therefore not be Zariski dense. Hence, the proposition applies in particular to Zariski dense τ_{mod} -regular subgroups.

(ii) Essentially the same notion of limit set had been introduced and studied by Benoist in [Ben]. He showed that for Zariski dense subgroups Γ the chamber limit set $\Lambda_{\sigma_{mod}}(\Gamma)$ (and hence every τ_{mod} -limit set) is nonempty, perfect and the Γ -action on it is minimal, see [Ben, 3.6]. Furthermore, the attractive fixed points of the proximal elements in Γ , cf. Remark 5.10, lie dense in the limit set. The minimality of the Γ -action on $\Lambda_{\sigma_{mod}}(\Gamma)$ implies that the intersection of the visual limit set $\Lambda(\Gamma)$ with every limit chamber $\sigma \in \Lambda_{\sigma_{mod}}(\Gamma)$ is independent of σ modulo the canonical mutual identifications of Weyl chambers, in other words, the set of types $l(\Gamma) := \theta(\sigma \cap \Lambda(\Gamma)) \subset \sigma_{mod}$ is independent. One of the main results of [Ben] regarding the structure of limit sets of Zariski dense subgroups Γ asserts that $l(\Gamma)$ is convex with nonempty interior, see [Ben, 1.2-1.3]. (We will not use this result in our paper.) In particular, if Γ is uniformly regular and Zariski dense in G , then $\Lambda(\Gamma)$ is Γ -equivariantly homeomorphic to the product $l(\Gamma) \times \Lambda_{\sigma_{mod}}(\Gamma)$. This product decomposition comes from the fact that $\partial_{\infty}^{reg} X$ splits naturally as the product of $\partial_F X$ and the open simplex $\text{int}(\sigma_{mod})$. We note that the Zariski density assumption not used in our paper, is essential to Benoist's work. On the other hand, τ_{mod} -regularity assumptions which are key for us, play no role in [Ben].

(iii) There are other notions of limit sets for actions of discrete subgroups of G on partial flag manifolds, see [CNS] for details.

Remark 5.36. We recall that the limit set of a discrete isometry group of a rank 1 symmetric space either consists of ≤ 2 points or has cardinality of continuum. Situation in the case of symmetric spaces of rank ≥ 2 is different: It may happen that flag limit set is finite with more than two points. For a specific example, let $\Gamma \subset G$ be a virtually abelian discrete subgroup which preserves a maximal flat $F \subset X$, and acts on F cocompactly and such that the action $\Gamma \curvearrowright \partial_{\infty} F$ is via the Weyl group of G . Then for every face type τ_{mod} the flag limit set $\Lambda_{\tau_{mod}}(\Gamma)$ is finite and consists of the type τ_{mod} flags in $\partial_{\infty} F$. Clearly, the group Γ therefore satisfies the assumptions of the first part of Proposition 5.34.

5.5 Antipodal subgroups

In the remainder of this paper, we will only consider weakly regular subgroups whose limit set satisfies the following natural additional property.

Definition 5.37 (Antipodal). A subset of $\text{Flag}(\tau_{mod})$ is *antipodal* if it consists of pairwise

opposite simplices. A discrete subgroup $\Gamma \subset G$ is τ_{mod} -antipodal if $\Lambda_{\tau_{mod}}(\Gamma)$ is antipodal.

It would be nice to know whether or not weak regularity implies antipodality. We currently have no examples of τ_{mod} -regular discrete subgroup $\Gamma \subset G$ which are not τ_{mod} -antipodal.

For antipodal subgroups, the attraction-repulsion dynamics on flag manifolds as given by Proposition 5.29 implies convergence dynamics on the limit set (also without the assumption of weak regularity). We obtain the following version of Proposition 5.34:

Proposition 5.38 (Dynamical properties of antipodal subgroups). *Let $\Gamma \subset G$ be a τ_{mod} -antipodal discrete subgroup. Then the action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$ is a convergence action.*

If in addition $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$, then the convergence action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$ is minimal and $\Lambda_{\tau_{mod}}(\Gamma)$ is perfect.

Proof. The argument is similar to the proof of Proposition 5.34. Let $\lambda_+ \in \Lambda_{\tau_{mod}}(\Gamma)$, and let (γ_n) be a τ_{mod} -regular sequence in Γ such that $\gamma_n^{\pm 1} \rightarrow \lambda_{\pm}$ locally uniformly on $C(\lambda_{\mp})$ with $\lambda_- \in \Lambda_{\tau_{mod}}(\Gamma)$. Due to antipodality, $\Lambda_{\tau_{mod}}(\Gamma) \cap C(\lambda_{\mp}) = \Lambda_{\tau_{mod}}(\Gamma) - \{\lambda_{\mp}\}$. This establishes the convergence property.

If $\Lambda_{\tau_{mod}}(\Gamma)$ has at least three points, the minimality of the Γ -action on $\Lambda_{\tau_{mod}}(\Gamma)$ and the perfectness of $\Lambda_{\tau_{mod}}(\Gamma)$ follow from results by Gehring-Martin and Tukia, cf. Proposition 3.8. \square

Remark 5.39. Under the assumptions of the proposition, let $A \subset \text{Flag}(\tau_{mod})$ be a nonempty Γ -invariant compact antipodal subset. Then $\Lambda_{\tau_{mod}}(\Gamma) \subset A$, compare Proposition 5.34, and $\Gamma \curvearrowright A$ is a convergence action. The argument is the same as in the proof of the last proposition.

6 Asymptotic conditions for discrete subgroups

6.1 Conicality

6.1.1 Conical convergence

Following the notion of conical convergence at infinity for sequences in rank one symmetric spaces, we will say that a flag converging sequence converges *conically* if it goes straight towards its limit flag in a suitable sense. In the context of flag convergence it is natural to require the sequence to stay within bounded distance not from a geodesic ray but from the Weyl cone over the star of its limit flag.

Definition 6.1 (Conical convergence). We say that a τ_{mod} -converging sequence in X converges *conically* to its limit flag $\tau \in \text{Flag}(\tau_{mod})$ if it is contained in a certain tubular neighborhood of the Weyl cone $V(x, \text{st}(\tau))$. Similarly, we say that a τ_{mod} -converging sequence (g_n) in G converges *conically* if an (y) orbit $(g_n x)$ in X converges conically.

In other words, the convergence of a sequence in X or G is conical with limit flag τ if and only if the constant sequence (τ) is a shadow sequence.

We will need later the following observation.

Lemma 6.2. *A flag converging sequence $x_n \xrightarrow{f} \tau$ converges conically if and only if it is contained in a tubular neighborhood of a parallel set $P(\tau, \hat{\tau})$ for some simplex $\hat{\tau}$ opposite to τ .*

Proof. Suppose that (x_n) is contained in a tubular neighborhood of $P(\tau, \hat{\tau})$. Then there exist ideal points $\xi_n \in \partial_\infty P(\tau, \hat{\tau})$ such that x_n has uniformly bounded distance from the rays $x\xi_n$, where $x \in P(\tau, \hat{\tau})$ is some base point. Since $\partial_\infty P(\tau, \hat{\tau})$ is a top-dimensional subbuilding of $\partial_\infty X$, the points ξ_n are contained in chambers $\sigma_n \subset \partial_\infty P(\tau, \hat{\tau})$. The type τ_{mod} faces of these chambers then form a shadow sequence of (x_n) . Hence there exists a shadow sequence (τ_n) of (x_n) consisting of simplices $\tau_n \subset \partial_\infty P(\tau, \hat{\tau})$. Since τ is isolated among the type τ_{mod} simplices in $\partial_\infty P(\tau, \hat{\tau})$, compare Lemma 2.9, the convergence $\tau_n \rightarrow \tau$ implies that $\tau_n = \tau$ for large n . \square

6.1.2 Recognizing conical convergence at infinity

As it is the case for flag convergence, also the conicality of the convergence can be read off the dynamics at infinity, namely it can be recognized from the dynamics on pairs of flags.

Suppose that the sequence (g_n) in G flag converges, $g_n \xrightarrow{f} \tau$. Then there exists a contraction sequence for (g_n^{-1}) which exhausts $C(\tau)$, cf. Lemma 5.28. Hence the orbits $(g_n^{-1}\hat{\tau})$ for all simplices $\hat{\tau} \in C(\tau)$ are asymptotic to each other. (More generally, this remains true for all sequences $(g_n^{-1}\hat{\tau}_n)$ where $(\hat{\tau}_n)$ is a bounded sequence in $C(\tau)$.) However, there is in general no control on the asymptotics of the orbits of the other simplices $\tau' \in \text{Flag}(\tau_{mod}) - C(\tau)$, in particular of the orbit $(g_n^{-1}\tau)$.

We will now see that $g_n \xrightarrow{f} \tau$ conically if and only if the orbit $(g_n^{-1}\tau)$ stays away from the orbits $(g_n^{-1}\hat{\tau})$ for $\hat{\tau} \in C(\tau)$ in the sense that the sequence of pairs $g_n^{-1}(\tau, \hat{\tau})$ is bounded in the space

$$(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp} \subset \text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod})$$

of pairs of opposite flags of type $\tau_{mod} = \theta(\tau)$.

Lemma 6.3. *A set of opposite pairs $A \subset (\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$ is bounded if and only if the corresponding family of parallel sets $P(\tau_-, \tau_+)$ in X for $(\tau_-, \tau_+) \in A$ is bounded, i.e.*

$$\sup_{(\tau_-, \tau_+) \in A} d(x, P(\tau_-, \tau_+)) < +\infty$$

for a base point x .

Proof. The forward direction can be deduced from the fact that $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$ is a homogeneous G -space. Indeed, if A is bounded, then there exists a compact subset $C \subset G$ and a reference pair $a_0 = (\tau_0^-, \tau_0^+)$ such that $A \subset Ca_0$. It follows that the parallel sets $P(\tau_-, \tau_+)$ for $(\tau_-, \tau_+) \in A$ intersect the compact set Cx_0 , where x_0 is a point in $P(\tau_0^-, \tau_0^+)$.

For the converse direction we use that the set of triples (τ_-, x', τ_+) , such that τ_\pm are simplices of type τ_{mod} opposite to each other with respect to the point $x' \in X$, is still a homogeneous G -space. As a consequence, every parallel set $P(\tau_-, \tau_+)$ intersecting the ball $B(x_0, R)$ is of the form

$gP(\tau_0^-, \tau_0^+)$ with g such that $d(x_0, gx_0) \leq R$, i.e. g belongs to a compact subset of G . It follows that the set of these pairs $(\tau_-, \tau_+) = g(\tau_0^-, \tau_0^+)$ is bounded in $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$. \square

Proposition 6.4 (Recognizing conical convergence at infinity). *Suppose that the sequence (g_n) in G flag converges, $g_n \xrightarrow{f} \tau$. Then the following are equivalent:*

- (i) $g_n \xrightarrow{f} \tau$ conically.
- (ii) For some flag $\hat{\tau} \in C(\tau)$, the sequence of pairs $g_n^{-1}(\tau, \hat{\tau})$ is bounded in $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$.
- (ii') For any bounded sequence $(\hat{\tau}_n)$ in $C(\tau)$, the sequence of pairs $g_n^{-1}(\tau, \hat{\tau}_n)$ is bounded in $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$.

Proof. Let $(\hat{\tau}_n)$ be a bounded sequence in $C(\tau)$, i.e. as a subset it is relatively compact. Then the set of pairs $(\tau, \hat{\tau}_n)$ is bounded in $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$, and hence the family of parallel sets $P(\tau, \hat{\tau}_n)$ is bounded, i.e.

$$\sup_n d(x, P(\tau, \hat{\tau}_n)) < +\infty$$

for a base point x , cf. Lemma 6.3. We have the estimate

$$d(x, g_n^{-1}P(\tau, \hat{\tau}_n)) = d(g_n x, P(\tau, \hat{\tau}_n)) \leq d(g_n x, V(x, \text{st}(\tau))) + d(x, P(\tau, \hat{\tau}_n)),$$

using that $\text{st}(\tau) \subset \partial_\infty P(\tau, \hat{\tau}_n)$ and hence $d(\cdot, P(\tau, \hat{\tau}_n))|_{V(x, \text{st}(\tau))}$ is maximal at x .

The right hand side is bounded iff $g_n \rightarrow \tau$ conically. The left hand side is bounded iff the sequence of pairs $g_n^{-1}(\tau, \hat{\tau}_n)$ is bounded in $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$, again by Lemma 6.3. This shows the implication (i) \Rightarrow (ii').

Conversely, assume the weaker condition (ii). Then the sequence $(g_n x)$ is contained in a tubular neighborhood of $P(\tau, \hat{\tau})$ and Lemma 6.2 implies (i). \square

6.1.3 Conical limit set

Conicality is a condition on the asymptotic geometry of the orbits of a discrete subgroup $\Gamma \subset G$, namely on how limit flags can be approached by sequences in orbits $\Gamma x \subset X$.

Following the definition of conicality in the rank one case, cf. section 4, a limit point $\xi \in \Lambda(\Gamma) \subset \partial_\infty X$ may be called *ray conical* if it is the limit of a sequence of orbit points $\gamma_n x$ which are contained in a tubular neighborhood of some geodesic ray asymptotic to ξ . However, ray conicality too restrictive in higher rank. It is satisfied by convex-cocompact subgroups, but these are rare, cf. [KL06], and e.g. one can show that RCA Schottky subgroups are, in general, not ray conical, see section 7.6 for the construction.

The following notion of conicality considered by Albuquerque [Al, Def. 5.2] is more flexible and useful in higher rank.

Definition 6.5 (Conical limit set). Let $\Gamma \subset G$ be a discrete subgroup. We call a limit flag $\lambda \in \Lambda_{\tau_{mod}}(\Gamma)$ *conical* if there exists a τ_{mod} -regular sequence (γ_n) in Γ such that $\gamma_n \xrightarrow{f} \lambda$

conically. The *conical τ_{mod} -limit set* $\Lambda_{\tau_{mod}}^{con}(\Gamma) \subset \Lambda_{\tau_{mod}}(\Gamma)$ is the subset of conical limit flags. We say that Γ has *conical τ_{mod} -limit set* or is *τ_{mod} -conical* if $\Lambda_{\tau_{mod}}(\Gamma) = \Lambda_{\tau_{mod}}^{con}(\Gamma)$.

We deduce from Proposition 6.4 how one can recognize conical limit flags from the dynamics at infinity, compare the notion of intrinsically conical point in the case of convergence actions cf. Definition 3.4.

Lemma 6.6 (Recognizing conical limit flags). *A flag $\tau \in \text{Flag}(\tau_{mod})$ is a conical limit flag if and only if there exists a τ_{mod} -regular sequence (γ_n) in Γ such that*

- (i) *the maps $\gamma_n^{-1}|_{C(\tau)}$ converge locally uniformly to a constant map, $\gamma_n^{-1}|_{C(\tau)} \rightarrow \hat{\tau}_-$, and*
- (ii) *the points $\gamma_n^{-1}\tau$ converge, $\gamma_n^{-1}\tau \rightarrow \tau_-$, with limit τ_- opposite to $\hat{\tau}_-$.*

Proof. Let τ be a conical limit flag. Then there exists a τ_{mod} -regular sequence (γ_n) in Γ such that $\gamma_n \xrightarrow{f} \tau$ conically. By passing to a subsequence we can obtain further convergence properties, namely that also the sequence (γ_n^{-1}) flag converges (not necessarily conically), $\gamma_n^{-1} \xrightarrow{f} \hat{\tau}_-$, and that $\gamma_n^{-1}\tau \rightarrow \tau_-$. Then Proposition 5.29 yields that $\gamma_n^{-1}|_{C(\tau)} \rightarrow \hat{\tau}_-$ locally uniformly.

To see that the flags τ_- and $\hat{\tau}_-$ are opposite, we use Proposition 6.4. For any flag $\hat{\tau} \in C(\tau)$ we have the convergence of pairs $\gamma_n^{-1}(\tau, \hat{\tau}) \rightarrow (\tau_-, \hat{\tau}_-)$. On the other hand, the proposition implies that the sequence $\gamma_n^{-1}(\tau, \hat{\tau})$ is relatively compact in the space of opposite pairs $(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}$. Hence the limit pair $(\tau_-, \hat{\tau}_-)$ must also lie in this space, i.e. τ_- and $\hat{\tau}_-$ are opposite.

Conversely, suppose that (γ_n) is a τ_{mod} -regular sequence in Γ satisfying (i) and (ii). Then property (i) implies flag convergence $\gamma_n \xrightarrow{f} \tau$, compare Lemma 5.28, and we can apply Proposition 6.4. It follows that $\gamma_n \xrightarrow{f} \tau$ conically. \square

Remark 6.7. As mentioned in the proof, property (i) implies flag convergence $\gamma_n \xrightarrow{f} \tau$, compare Lemma 5.28, and in particular that τ is a limit flag, $\tau \in \Lambda_{\tau_{mod}}(\Gamma)$.

6.1.4 Comparing extrinsic and intrinsic conicality

If $\Gamma \subset G$ is a τ_{mod} -antipodal discrete subgroup, then $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$ is a convergence action, cf. Proposition 5.38, and hence there is a notion of intrinsic conical point for this action, cf. Definition 3.4. We show now that the intrinsic and extrinsic notions of conicality coincide for non-elementary weakly regular antipodal subgroups:

Proposition 6.8 (Conical equivalent to intrinsically conical). *Let $\Gamma \subset G$ be a τ_{mod} -antipodal τ_{mod} -regular discrete subgroup and suppose that $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$.*

Then a limit flag in $\Lambda_{\tau_{mod}}(\Gamma)$ is conical if and only if it is intrinsically conical for the convergence action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$.

Proof. Suppose that the limit flag $\lambda \in \Lambda_{\tau_{mod}}(\Gamma)$ is conical. Then it follows by restricting the Γ -action on $\text{Flag}(\tau_{mod})$ to the convergence action on $\Lambda_{\tau_{mod}}(\Gamma)$ and applying Lemma 6.6, that λ is intrinsically conical.

Conversely, suppose that λ is intrinsically conical for the convergence action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$. Then there exist a sequence $\gamma_n \rightarrow \infty$ in Γ and a pair of opposite limit flags in $\lambda_-, \hat{\lambda}_- \in \Lambda_{\tau_{mod}}(\Gamma)$ such that $\gamma_n^{-1}\lambda \rightarrow \lambda_-$ and $\gamma_n^{-1}|_{\Lambda_{\tau_{mod}}(\Gamma) - \{\lambda\}} \rightarrow \hat{\lambda}_-$ locally uniformly. Note that $\Lambda_{\tau_{mod}}(\Gamma) - \{\lambda\} \neq \emptyset$ because $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$.

Now we consider the Γ -action on the entire flag manifold $\text{Flag}(\tau_{mod})$. By assumption, Γ is τ_{mod} -regular, and hence in particular the sequence (γ_n) . After passing to a subsequence, we may assume that $\gamma_n^{\pm 1} \xrightarrow{f} \tau_{\pm} \in \text{Flag}(\tau_{mod})$, and therefore

$$\gamma_n^{\pm 1}|_{C(\tau_{\mp})} \rightarrow \tau_{\pm}$$

locally uniformly, as a consequence of Proposition 5.29. Necessarily, $\tau_{\pm} \in \Lambda_{\tau_{mod}}(\Gamma)$.

We first observe that $\tau_+ = \lambda$. Indeed, assume that $\tau_+ \neq \lambda$. Then $\Lambda_{\tau_{mod}}(\Gamma) - \{\lambda\}$ and $C(\tau_+)$ cover $\Lambda_{\tau_{mod}}(\Gamma)$. Since $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$, they also intersect and it follows that γ_n^{-1} converges uniformly on the entire limit set $\Lambda_{\tau_{mod}}(\Gamma)$ to a constant map, which is absurd. So, $\gamma_n \xrightarrow{f} \lambda$.

Now we can apply Proposition 6.4. For every limit flag $\hat{\lambda} \in \Lambda_{\tau_{mod}}(\Gamma) - \{\lambda\} \subset C(\lambda)$ we have $\gamma_n^{-1}(\lambda, \hat{\lambda}) \rightarrow (\lambda_-, \hat{\lambda}_-)$. Such limit flags $\hat{\lambda} \neq \lambda$ exist, and implication (ii) \Rightarrow (i) of the proposition yields that $\gamma_n \xrightarrow{f} \lambda$ conically, i.e. λ is conical. \square

6.1.5 Expansion at conical limit flags

If a weakly regular sequence (g_n) in G flag converges, $g_n \xrightarrow{f} \tau \in \text{Flag}(\tau_{mod})$, then its sequence (g_n^{-1}) of inverses admits an expansion sequence (V_n^-) in $\text{Flag}(\tau_{mod})$ with $V_n^- \rightarrow \tau$, see Proposition 5.14(ii). We will show now that, if the convergence is conical, then there is a stronger form of expansion at τ for the dynamics of (g_n^{-1}) on $\text{Flag}(\tau_{mod})$.

Generalizing the definition of expansion point for a group action, cf. Definition 3.1, from groups to sequences, we say that the sequence (g_n^{-1}) in G is *expanding* on $\text{Flag}(\tau_{mod})$ at τ if

$$\lim_{n \rightarrow +\infty} \epsilon(g_n^{-1}, \tau) = +\infty$$

with respect to an auxiliary Riemannian metric on $\text{Flag}(\tau_{mod})$. This implies in particular that for large n the map g_n^{-1} is uniformly expanding on some neighborhood V_n of τ in $\text{Flag}(\tau_{mod})$ with expansion factor $c_n \rightarrow +\infty$.

Lemma 6.9. *If a τ_{mod} -regular sequence (g_n) in G flag converges conically, $g_n \xrightarrow{f} \tau \in \text{Flag}(\tau_{mod})$, then the sequence (g_n^{-1}) is expanding at τ .*

Proof. By assumption, the orbit sequence $(g_n x)$ for a point $x \in X$ is contained in a tubular neighborhood of the Weyl cone $V(x, \text{st}(\tau))$ and, due to τ_{mod} -regularity, we have that

$$\lim_{n \rightarrow +\infty} d(g_n x, \partial V(x, \text{st}(\tau))) = +\infty.$$

Corollary 2.55 implies that the infinitesimal expansion of g_n^{-1} at τ becomes arbitrarily strong,

$$\lim_{n \rightarrow +\infty} \epsilon(g_n^{-1}, \tau) = +\infty$$

(with respect to the auxiliary Riemannian metric on $\text{Flag}(\tau_{mod})$). Thus for sufficiently large n , the map g_n^{-1} is uniformly expanding with arbitrarily large expansion factor on some neighborhood of τ . \square

Applied to group actions, the lemma yields:

Proposition 6.10 (Expansion at conical limit flags). *Let $\Gamma \subset G$ be a discrete subgroup. If the limit flag $\lambda \in \Lambda_{\tau_{mod}}(\Gamma)$ is conical, then the action $\Gamma \curvearrowright \text{Flag}(\tau_{mod})$ is expanding at λ . In particular, if Γ has conical flag limit set $\Lambda_{\tau_{mod}}(\Gamma)$, then the action $\Gamma \curvearrowright \text{Flag}(\tau_{mod})$ is expanding at $\Lambda_{\tau_{mod}}(\Gamma)$.*

6.2 Equivalence of certain asymptotic conditions

In section 4, we discussed discrete groups of isometries on symmetric spaces of rank one and formulated a number of conditions (C2-C10) which are equivalent to convex cocompactness. We will now generalize some of these conditions to weakly regular discrete groups in arbitrary rank and show that they remain equivalent to each other.

The first condition generalizes the conical limit set property (C2) in rank one:

Definition 6.11 (RCA). We call a discrete subgroup of G τ_{mod} -RCA if it is τ_{mod} -regular, τ_{mod} -conical and τ_{mod} -antipodal. We call it *weakly RCA* if it is τ_{mod} -RCA for some τ_{mod} , and *RCA* if it is σ_{mod} -RCA.

In this section we prove that weakly RCA groups are word hyperbolic and that their τ_{mod} -limit set is equivariantly homeomorphic to their Gromov boundary. We will also prove a converse of this result and establish a similar equivalence of between weak RCA and an expansion property (subject to τ_{mod} -regularity and antipodality conditions).

The second condition generalizes condition C6 in rank one, requesting that the subgroup is intrinsically word hyperbolic and its limit set is an equivariantly embedded copy of its Gromov boundary as a word hyperbolic group:

Definition 6.12 (Asymptotically embedded). We call an τ_{mod} -antipodal τ_{mod} -regular discrete subgroup $\Gamma \subset G$ τ_{mod} -asymptotically embedded if Γ is word hyperbolic and there exists a Γ -equivariant homeomorphism

$$\alpha : \partial_{\infty}\Gamma \xrightarrow{\cong} \Lambda_{\tau_{mod}}(\Gamma) \subset \text{Flag}(\tau_{mod}) \tag{6.13}$$

of its Gromov boundary onto its τ_{mod} -limit set.

Note that in view of the minimality of the action on the flag limit set, cf. Proposition 5.38, it suffices to assume that α is an equivariant embedding into $\Lambda_{\tau_{mod}}(\Gamma)$.

The terminology ‘‘asymptotically embedded’’ is justified by the next observation which can be understood as saying that for asymptotically embedded subgroups the orbit maps $\Gamma \rightarrow \Gamma x \subset X$ continuously extend to maps $\bar{\Gamma} \rightarrow X \cup \text{Flag}(\tau_{mod})$ from the visual compactification of the group to the bordification of X :

Lemma 6.14 (Continuity at infinity). *Suppose that $\Gamma \subset G$ is τ_{mod} -asymptotically embedded and $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$. Then a sequence $\gamma_n \rightarrow \infty$ in Γ converges to $\zeta \in \partial_\infty \Gamma$ if and only if, as a sequence in G , it flag converges to $\alpha(\zeta) \in \Lambda_{\tau_{mod}}(\Gamma)$.*

Note that the assertion may fail when Γ is elementary (as a hyperbolic group), for instance when Γ is cyclic and hence acts trivially on its ideal boundary $\partial_\infty \Gamma$ which consists of two points.

Proof. We use the characterization of flag convergence in terms of the dynamics at infinity and the analogous fact for hyperbolic groups.

Suppose that the assertion is wrong. Then there exists a sequence $\gamma_n \rightarrow \infty$ in Γ such that $\gamma_n \rightarrow \zeta$ in $\bar{\Gamma}$ and $\gamma_n \xrightarrow{f} \lambda \in \Lambda_{\tau_{mod}}(\Gamma)$ in G , but $\lambda \neq \alpha(\zeta)$. According to Lemma 5.28, this means that (γ_n^{-1}) admits contraction sequences (U_n) on $\text{Flag}(\tau_{mod})$ opposite to λ , $U_n \subset C(\lambda)$, and (U'_n) on $\partial_\infty \Gamma$ opposite to ζ , $U'_n \subset \partial_\infty \Gamma - \{\zeta\}$. Due to antipodality, $(\alpha^{-1}(U_n))$ is another contraction sequence on $\partial_\infty \Gamma$, but opposite to $\alpha^{-1}(\lambda) \neq \zeta$. It follows that for large n the subsets U'_n and $\alpha^{-1}(U_n)$ cover $\partial_\infty \Gamma$ and, since $|\partial_\infty \Gamma| = |\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$, intersect. This implies that $\gamma_n^{-1}(\partial_\infty \Gamma)$ shrinks to a point, a contradiction. \square

Our third condition extends the expansion at the limit set property (C10) to higher rank:

Definition 6.15 (Expanding at infinity). We call a τ_{mod} -antipodal τ_{mod} -regular discrete subgroup $\Gamma \subset G$ τ_{mod} -expanding at infinity if the action $\Gamma \curvearrowright \text{Flag}(\tau_{mod})$ is expanding at $\Lambda_{\tau_{mod}}(\Gamma)$ (with respect to a Riemannian background metric).

We note that it is plausible that in the three definitions above the antipodality assumption is implied by regularity and hence redundant.

Theorem 6.16 (Equivalence of asymptotic conditions). *Suppose that $\Gamma \subset G$ is a τ_{mod} -antipodal τ_{mod} -regular discrete subgroup such that $|\Lambda_{\tau_{mod}}(\Gamma)| \geq 3$. Then the following are equivalent:*

- (i) Γ is τ_{mod} -RCA.
- (ii) Γ is τ_{mod} -asymptotically embedded.
- (iii) Γ is τ_{mod} -expanding at infinity.

Proof. Due to the equivalence of the intrinsic and extrinsic notions of conicality, see Proposition 6.8, property (i) is equivalent to $\Lambda_{\tau_{mod}}(\Gamma)$ being intrinsically conical for the convergence action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$.

Suppose that $\Lambda_{\tau_{mod}}(\Gamma)$ is intrinsically conical. According to Proposition 5.38, $\Lambda_{\tau_{mod}}(\Gamma)$ is perfect. Therefore, we can apply Bowditch's Theorems 3.5 and 3.3. ($\Lambda_{\tau_{mod}}(\Gamma)$ is metrizable as a subset of the manifold $\text{Flag}(\tau_{mod})$.) Theorem 3.5 implies that the convergence action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$ is uniform, and Theorem 3.3 implies property (ii). The converse implication holds because the action of a word hyperbolic group on its Gromov boundary is intrinsically conical. Hence (i) and (ii) are equivalent.

The equivalence with (iii) can be seen as follows. The (extrinsic) conicality of $\Lambda_{\tau_{mod}}(\Gamma)$

implies that the action $\Gamma \curvearrowright \text{Flag}(\tau_{mod})$ is expanding at $\Lambda_{\tau_{mod}}(\Gamma)$, see Lemma 6.9. Vice versa, if the action $\Gamma \curvearrowright \Lambda_{\tau_{mod}}(\Gamma)$ is expanding, then $\Lambda_{\tau_{mod}}(\Gamma)$ is intrinsically conical by Lemma 3.7. \square

Corollary 6.17. *If $\Gamma \subset G$ is τ_{mod} -RCA or τ_{mod} -expanding at infinity, then it is word hyperbolic.*

6.3 Boundary embeddings

The asymptotic embedding property requires an equivariant embedding from the Gromov boundary to the τ_{mod} -limit set of an intrinsically word hyperbolic τ_{mod} -regular discrete subgroup. In this section we consider a weakening of this property.

Definition 6.18 (Boundary embedded). Let Γ be a non-elementary (i.e. not virtually cyclic) word hyperbolic group. We say that an isometric action $\rho : \Gamma \curvearrowright X$ is τ_{mod} -boundary embedded if there exists a Γ -equivariant continuous embedding

$$\beta : \partial_{\infty}\Gamma \rightarrow \text{Flag}(\tau_{mod}). \tag{6.19}$$

which maps different boundary points to opposite flags.

Note that such actions are necessarily properly discontinuous, because Γ acts on $\beta(\partial_{\infty}\Gamma)$ as a discrete convergence group. Henceforth, we identify Γ with its image in G .

Note moreover, that we do not a priori assume that the subgroup $\Gamma \subset G$ is τ_{mod} -regular. Even if it is τ_{mod} -regular, boundary embeddedness is a priori weaker than asymptotic embeddedness, because it does not assume that $\beta(\partial_{\infty}\Gamma) \subseteq \Lambda_{\tau_{mod}}(\Gamma)$ or that Γ is τ_{mod} -antipodal. Nevertheless, in the case $\tau_{mod} = \sigma_{mod}$ we will show that being boundary embedded and regular implies the stronger asymptotic embeddedness property, see Proposition 6.24 below. Furthermore, one can show the same implication for arbitrary τ_{mod} and Zariski dense subgroups (cf. [GW]), but we will not prove this in our paper.

Note also that for τ_{mod} -asymptotically embedded groups there are in general other equivariant embeddings $\partial_{\infty}\Gamma \rightarrow \text{Flag}(\tau_{mod})$ besides the one onto the τ_{mod} -limit set, even if $\tau_{mod} = \sigma_{mod}$:

Example 6.20 (Nonuniqueness of boundary maps). One can construct totally geodesic embeddings $Y \hookrightarrow X$ of symmetric spaces, e.g. of equal rank ≥ 2 , such that for the induced boundary map at infinity $\partial_{\infty}Y \hookrightarrow \partial_{\infty}X$ Weyl chambers of Y break up into several Weyl chambers of X . Then there are several induced embeddings $\partial_F Y \hookrightarrow \partial_F X$ of Fürstenberg boundaries. As a consequence, for suitable hyperbolic groups Γ acting on Y one obtains several equivariant embeddings $\partial_{\infty}\Gamma \hookrightarrow \partial_F X$.

For instance, consider the embedding of Weyl groups $W_{A_1 \circ A_1} \subset W_{B_2}$ and the corresponding refinement of Coxeter complexes where an $A_1 \circ A_1$ -Weyl arc of length $\frac{\pi}{2}$ breaks up into two B_2 -Weyl arcs of length $\frac{\pi}{4}$. Let $Y \hookrightarrow X$ be an isometric embedding of symmetric spaces inducing this embedding of Weyl groups, and $H \subset G$ a corresponding embedding of semisimple Lie groups, for instance, $SO(2, 1) \times SO(2, 1) \subset SO(4, 2)$. The symmetric space Y is reducible and decomposes as a product of rank one spaces, $Y \cong Y_1 \times Y_2$. Accordingly, its Tits boundary decomposes as a spherical join, $\partial_{Tits} Y \cong \partial_{Tits} Y_1 \circ \partial_{Tits} Y_2$. The Weyl chambers of Y are arcs

$\xi_1 \circ \xi_2$ of length $\frac{\pi}{2}$ with endpoints $\xi_i \in \partial_\infty Y_i$. The embedding $\partial_\infty Y \hookrightarrow \partial_\infty X$ of visual boundaries sends the Weyl chamber $\xi_1 \circ \xi_2$ to an arc denoted by $\xi_1 \xi_2$. With respect to the spherical building structure on $\partial_\infty X$ it decomposes as the union of two Weyl chambers $\xi_i \mu$ of length $\frac{\pi}{4}$, where μ is the midpoint of $\xi_1 \xi_2$. We see that there are *two* H -equivariant continuous embeddings of Fürstenberg boundaries $\iota_i : \partial_F Y \hookrightarrow \partial_F X$ obtained by assigning to each Weyl chamber $\xi_1 \circ \xi_2$ of Y its half $\xi_i \mu$ of type i . The embeddings send opposite chambers to opposite chambers. It is easy to construct regular Schottky subgroups $\Gamma \subset H$ which remain regular in G , and by composing the embeddings $\partial_\infty \Gamma \rightarrow \partial_F Y$ with ι_i , one obtains two Γ -equivariant embeddings $\partial_\infty \Gamma \rightarrow \partial_F X$ mapping distinct boundary points to opposite chambers.

6.4 Coarse extrinsic geometry

In this section we study the coarse geometry of discrete subgroups $\Gamma \subset G$ satisfying one of the asymptotic conditions introduced above, i.e. one of the three equivalent conditions ‘‘RCA’’, ‘‘asymptotically embedded’’ and ‘‘expanding at infinity’’ or the weaker condition ‘‘boundary embedded’’. Note that such subgroups are intrinsically word hyperbolic and hence finitely generated, see Corollary 6.17 and Definition 6.18. We will show that RCA subgroups are undistorted, i.e. that the orbit maps $\Gamma \rightarrow \Gamma x \subset X$ are quasi-isometric embeddings. Equivalently, they send uniform quasigeodesics in Γ to uniform quasigeodesics in X . We will in fact prove a stronger form of undistortion, namely that the images of quasigeodesics in Γ under the orbit maps satisfy a generalized version of the Morse Lemma (for quasigeodesics in negatively curved spaces): the images of quasirays stay close to Weyl cones. This is indeed a strong further restriction because in higher rank quasigeodesics are quite flexible.

6.4.1 Boundary embedded groups

In this section we consider boundary embedded groups; this is a weakening of the asymptotic embeddedness which will be, however, sufficient for establishing some preliminary control on the images of quasigeodesics in Γ under the orbit maps, namely that they are uniformly close to parallel sets.

Let $\Gamma \subset G$ be a τ_{mod} -boundary embedded discrete subgroup. The boundary map $\beta : \partial_\infty \Gamma \rightarrow \text{Flag}(\tau_{mod})$ induces a map (β, β) of pairs of boundary points. By assumption, (β, β) maps pairs of distinct boundary points into the open dense G -orbit

$$(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp} \subset \text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod})$$

consisting of the pairs of opposite flags, and we obtain a continuous Γ -equivariant embedding

$$(\partial_\infty \Gamma \times \partial_\infty \Gamma) - \text{Diag} \xrightarrow{(\beta, \beta)} (\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp}.$$

Here and in what follows, Diag denotes the diagonal in the product.

Lemma 6.21. *An (L, A) -quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$ with ideal endpoints $\zeta_\pm \in \partial_\infty \Gamma$ is mapped by the orbit map $\Gamma \rightarrow \Gamma x \subset X$ into a tubular neighborhood of uniform radius $r = r(\Gamma, L, A, x)$ of the parallel set $P(\beta(\zeta_-), \beta(\zeta_+))$.*

Proof. We consider the map from the space of (L, A) -quasigeodesics $q : \mathbb{Z} \rightarrow \Gamma$ to the space

$$(\text{Flag}(\tau_{mod}) \times \text{Flag}(\tau_{mod}))^{opp} \times X,$$

assigning to q the pair consisting of the (directed) parallel set $P(\beta(q(-\infty)), \beta(q(+\infty)))$ and the orbit point $q(0)x$. This map is Γ -equivariant and continuous, where the space of (L, A) -quasigeodesics is equipped with the topology of pointwise convergence. (The continuity of the assignment $q \mapsto (q(-\infty), q(+\infty))$ uses the Morse Lemma in the hyperbolic group Γ .) By composing this map with the distance between $q(0)x$ and the parallel set, we obtain a Γ -periodic continuous function on the space of (L, A) -quasigeodesics. Since Γ acts cocompactly on this space (by Arzela-Ascoli), this function is bounded. The assertion follows by shifting the parametrization of q . \square

6.4.2 The regular case

We restrict now to the case $\tau_{mod} = \sigma_{mod}$, i.e. we assume that the subgroup Γ is σ_{mod} -boundary embedded. In particular, it is then regular. Our proofs, while less general, will be more straightforward and motivate the more difficult arguments for general τ_{mod} and asymptotically embedded subgroups in section 6.4.3 below.

According to Lemma 6.21, the images of quasigeodesics in Γ under the orbit maps are now uniformly close to maximal flats; a quasigeodesic asymptotic to a pair of ideal points $\zeta_{\pm} \in \partial_{\infty}\Gamma$ is mapped into a tubular neighborhood of the maximal flat $F(\beta(\zeta_-), \beta(\zeta_+))$ asymptotic to the pair of opposite chambers $\beta(\zeta_-)$ and $\beta(\zeta_+)$. The next result restricts the position of the image along the maximal flat. Namely, the images of quasirays are uniformly close to euclidean Weyl chambers and move towards limit chambers at infinity:

Lemma 6.22. *There exists a Γ -equivariant embedding $\beta' : \partial_{\infty}\Gamma \rightarrow \Lambda_{\sigma_{mod}}(\Gamma) \subset \partial_F X$ sending distinct ideal points to antipodal chambers, such that for every (L, A) -quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$ with ideal endpoints ζ_{\pm} we have*

$$(i) \beta'(\zeta_{\pm}) \subset \partial_{\infty}F(\beta(\zeta_-), \beta(\zeta_+)).$$

(ii) $q(m \pm n)x$ is contained in a tubular neighborhood of uniform radius $r' = r'(\Gamma, L, A, x)$ of the euclidean Weyl chamber $V(q(m)x, \beta'(\zeta_{\pm}))$ for $m, n \in \mathbb{N}$.

Proof. Let $q : \mathbb{Z} \rightarrow \Gamma$ be an (L, A) -quasigeodesic. By Lemma 6.21, $q(m \pm n)x$ is contained in the $r(\Gamma, L, A, x)$ -neighborhood of the maximal flat $F(\beta(\zeta_-), \beta(\zeta_+))$ and hence (by the triangle inequality) in the $2r(\Gamma, L, A, x)$ -neighborhood of the euclidean Weyl chamber $V(q(m)x, \sigma(m, \pm n))$ for some chamber $\sigma(m, \pm n) \subset \partial_{\infty}F(\beta(\zeta_-), \beta(\zeta_+))$.

The regularity of Γ implies that for every $D > 0$ we have

$$d(d_{\Delta}(x, \gamma x), \partial\Delta) \geq D \tag{6.23}$$

for all $\gamma \in \Gamma$ with $d_{\Gamma}(\gamma, e) \geq R = R(\Gamma, d_{\Gamma}, x, D)$. Here d_{Γ} denotes a word metric on Γ .

It follows that $\sigma(m, \pm n)$ stabilizes as $n \rightarrow +\infty$ independently of m , i.e. $\sigma(m, \pm n) = \sigma(m, \pm \infty)$ for $n \geq n(\Gamma, L, A, x)$. In particular, we have chamber convergence $q(m \pm n)x \xrightarrow{f}$

$\sigma(m, \pm\infty)$. Since any two asymptotic quasirays in Γ have finite Hausdorff distance from each other, the chamber limit $\sigma(m, \pm\infty)$ depends only on ζ_{\pm} . Putting $\beta'(\zeta_{\pm}) = \sigma(m, \pm\infty)$, we thus obtain a well-defined map $\beta' : \partial_{\infty}\Gamma \rightarrow \Lambda_{\sigma_{mod}}(\Gamma) \subset \partial_F X$ satisfying properties (i) and (ii).

The equivariance of β' is clear from the construction. To verify its continuity, we argue by contradiction. Suppose that $\zeta_k \rightarrow \zeta$ in $\partial_{\infty}\Gamma$, but $\beta'(\zeta_k) \rightarrow \sigma \neq \beta'(\zeta)$ in $\partial_F X$. Since Γ is a word hyperbolic group, there exist uniform quasigeodesics $q_k : \mathbb{Z} \rightarrow \Gamma$ with $q_k(0) = 1_{\Gamma}$ and $q_k(+\infty) = \zeta_k$. After passing to a subsequence, we may assume that they converge (pointwise) to a quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$ with $q(0) = 1_{\Gamma}$ and $q(+\infty) = \zeta$. Then there exists a sequence of natural numbers $n_k \rightarrow +\infty$ such that the points $q_k(n_k)$ are contained in a tubular neighborhood of the quasiray $q(\mathbb{N})$, i.e. $q_k(n_k) \rightarrow \zeta$ conically. Using property (ii), it follows that both the sequence of chambers $(\beta'(\zeta_k))$ and the constant sequence $(\beta'(\zeta))$ are shadow sequences in $\partial_F X$ for the sequence $(q_k(n_k)x)$ of points in X . The asymptotic uniqueness of shadows (Lemma 5.15) implies that $\beta'(\zeta_k) \rightarrow \beta'(\zeta)$, contradicting our assumption. We conclude that β' is continuous.

It remains to verify that β' is antipodal. If $\zeta_{\pm} \in \partial_{\infty}\Gamma$ are distinct ideal points, then there exists a quasigeodesic q asymptotic to them, $q(\pm\infty) = \zeta_{\pm}$. For the nearest point projection \bar{q} of qx to $F(\beta(\zeta_-), \beta(\zeta_+))$ we have for large n that $\bar{q}(\pm n) \in V(\bar{q}(\mp n), \beta'(\zeta_{\pm}))$ and the segment $\bar{q}(-n)\bar{q}(n)$ is regular. This implies that the chambers $\beta'(\zeta_{\pm})$ are opposite to each other. \square

Using the information on quasirays, we can now show that the image of the modified boundary map β' fills out the chamber limit set. We conclude that the weaker asymptotic condition of boundary embeddedness already implies the stronger ones in the regular case:

Proposition 6.24 (Boundary embedded regular implies asymptotically embedded).

Every σ_{mod} -boundary embedded discrete subgroup $\Gamma \subset G$ is σ_{mod} -asymptotically embedded.

Proof. Lemma 6.22 yields that $\beta'(\partial_{\infty}\Gamma) \subseteq \Lambda_{\sigma_{mod}}(\Gamma)$. It suffices to prove that $\Lambda_{\sigma_{mod}}(\Gamma) = \beta'(\partial_{\infty}\Gamma)$.

The argument is similar to the proof of the continuity of β' in Lemma 6.22. Let $\sigma \in \Lambda_{\sigma_{mod}}(\Gamma)$ and let (γ_n) be a sequence in Γ chamber-converging to σ , $\gamma_n \xrightarrow{f} \sigma$. Since Γ is word hyperbolic, there exists a sequence of uniform quasigeodesics $q_n : \mathbb{Z} \rightarrow \Gamma$ such that $q_n(0) = 1_{\Gamma}$ and $\gamma_n \in q_n(\mathbb{N})$. Let $\zeta_n \in \partial_{\infty}\Gamma$ denote their forward ideal endpoints. According to Lemma 6.22, the distance from $\gamma_n x$ to the euclidean Weyl chamber $V(x, \beta'(\zeta_n))$ is uniformly bounded. Hence $(\beta'(\zeta_n))$ is a shadow of $(\gamma_n x)$ in $\partial_F X$, and Lemma 5.15 implies that $\beta'(\zeta_n) \rightarrow \sigma$. Thus $\sigma \in \beta'(\partial_{\infty}\Gamma)$. \square

Remark 6.25. (i) Since both embeddings β and β' are continuous and Γ -equivariant, the relative position (see [KLP]) $\text{pos}(\beta', \beta) : \partial_{\infty}\Gamma \rightarrow W$ is continuous (locally constant) and Γ -periodic. For nonelementary hyperbolic groups Γ this map must be constant, because the action of a nonelementary word hyperbolic group on its Gromov boundary is minimal.

(ii) One can show that if Γ is Zariski dense in G then $\beta = \beta'$, cf. [GW].

(iii) On the other hand, in general, β and β' can be different as Example 6.20 shows.

We take up again the discussion of the coarse geometry of the orbit map. Elaborating on

part (ii) of Lemma 6.22, we will see next that the images of quasirays, since they must stay close to euclidean Weyl chambers, they are forced to move out to infinity at a linear rate.

Definition 6.26 (Θ -regular quasigeodesic). Let $\Theta \subset \sigma_{mod}$ be a compact subset. A discrete quasigeodesic $p : I \cap \mathbb{Z} \rightarrow X$ is (s, Θ) -regular if for every $m, n \in I \cap \mathbb{Z}$ with $|m - n| \geq s$ the segment $p(m)p(n)$ is Θ -regular.

Lemma 6.27. For every (L, A) -quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$, its image qx in X is an (s, Θ) -regular discrete quasigeodesic with s , a compact subset $\Theta \subset \text{int}(\sigma_{mod})$ and quasi-isometry constants depending on Γ, L, A, x .

Proof. Since Γ is a discrete subgroup of G , the distance between orbit points can be bounded from below in terms of the word metric, i.e. there is an estimate of the form

$$d(\gamma x, \gamma' x) \geq f_x(d_\Gamma(\gamma, \gamma'))$$

with $f_x(t) \rightarrow +\infty$ as $t \rightarrow +\infty$. As a consequence, for $\rho > 0$ we have $d(q(m)x, q(m+n)x) \geq \rho$ for $n \geq n(f_x, L, A, \rho)$.

As before, let $\zeta_\pm \in \partial_\infty \Gamma$ denote the ideal endpoints of q . We consider the nearest point projection \bar{q} of qx to $F(\beta(\zeta_-), \beta(\zeta_+))$. Choosing $\rho \gg r(\Gamma, L, A, x), r'(\Gamma, L, A, x)$ and invoking again the regularity of Γ , cf. (6.23), we obtain as in the end of the proof of Lemma 6.22 that

$$\bar{q}(m \pm n) \in V(\bar{q}(m), \beta'(\zeta_\pm)) \tag{6.28}$$

for $n \geq n'(\Gamma, L, A, x)$. It follows that along the coarsening $\bar{q}|_{n'\mathbb{Z}}$ of \bar{q} , the Δ -distances between its points are additive in the sense that

$$d_\Delta(\bar{q}(m_1), \bar{q}(m_2)) + d_\Delta(\bar{q}(m_2), \bar{q}(m_3)) = d_\Delta(\bar{q}(m_1), \bar{q}(m_3)) \tag{6.29}$$

if $m_3 - m_2, m_2 - m_1 \geq n'$. In particular, \bar{q} and hence qx is a Θ -regular uniform quasigeodesic. \square

We summarize the properties of asymptotically embedded subgroups Γ established in the previous two lemmas:

(i) For some (every) $x \in X$ there exists a constant r such that for every discrete geodesic ray $q : \mathbb{N} \rightarrow \Gamma$, the points $q(n)x$ belong to the r -neighborhood of the Weyl cone $V(q(0)(x), \text{st}(\tau))$ for some $\tau \in \text{Flag}(\tau_{mod})$ depending on q .

(ii) For all sequences $\gamma_n \rightarrow \infty$ in Γ , all subsequential limits of the quantities

$$\frac{1}{|\gamma_n|} d_\Delta(x, \gamma_n x)$$

are in the interior of the cone $V(0, \text{st}(\tau_{mod}))$, where $|\gamma_n|$ denotes the word length of $\gamma_n \in \Gamma$.

As a consequence of Lemmata 6.22, 6.27, we obtain:

Theorem 6.30 (Coarse geometric properties of boundary embedded regular subgroups). Let $\Gamma \subset G$ be a σ_{mod} -boundary embedded discrete subgroup. Then Γ is σ_{mod} -asymptotically embedded, uniformly regular and the orbit maps $\Gamma \rightarrow \Gamma x \subset X$ are quasi-isometric embeddings.

Proof. Since Γ is word hyperbolic, through any two elements $\gamma, \gamma' \in \Gamma$ there exists a complete quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$ with uniform quasi-isometry constants L, A . The assertion then follows from Lemma 6.27. \square

6.4.3 Asymptotically embedded groups

In this section we prove a version of the results of the previous section for τ_{mod} -regular subgroups, under the stronger assumption of asymptotic embeddedness.

Let $\Gamma \subset G$ be τ_{mod} -asymptotically embedded, and let $\alpha : \partial_\infty \Gamma \rightarrow \Lambda_{\tau_{mod}}(\Gamma)$ be the equivariant homeomorphism. Lemma 6.21 holds for α . We will now obtain more specific information on the position of the image qx of the quasigeodesic q under the orbit map, generalizing Lemma 6.22(ii).

Lemma 6.31. *For every (L, A) -quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$ with ideal endpoints ζ_\pm , the point $q(m \pm n)x$ is contained in a tubular neighborhood of uniform radius $r'' = r''(\Gamma, L, A, x)$ of the Weyl cone $V(q(m)x, \text{st}(\alpha(\zeta_\pm)))$ for $m, n \in \mathbb{N}$.*

Proof. Due to the continuity at infinity of orbit maps (Lemma 6.14) we have that $q(n) \xrightarrow{f} \tau_+$ as $n \rightarrow +\infty$, where we abbreviate $\tau_\pm = \alpha(\zeta_\pm)$.

According to Lemma 6.21, qx is contained in a uniform tubular neighborhood of the parallel set $P(\tau_-, \tau_+)$. Therefore, the τ_{mod} -regular sequence $(q(n))$ in Γ has a shadow sequence (σ_n) in $\partial_F X$ consisting of chambers $\sigma_n \subset \partial_\infty P(\tau_-, \tau_+)$. Taking their type τ_{mod} faces, one obtains a shadow sequence (τ_n) in $\text{Flag}(\tau_{mod})$ consisting of simplices $\tau_n \subset \partial_\infty P(\tau_-, \tau_+)$. More precisely, $q(n)x$ has uniformly bounded distance from $V(q(0)x, \sigma_n) \subset V(q(0)x, \text{st}(\tau_n))$. The asymptotic uniqueness of shadows (Lemma 5.15) implies that $\tau_n \rightarrow \tau_+$.

We use now that τ_+ is isolated among the type τ_{mod} simplices occurring in $\partial_\infty P(\tau_-, \tau_+)$, see Lemma 2.9(i). It follows that $\tau_n = \tau_+$ for sufficiently large n . This means that the sequence $(q(n)x)$ enters a uniform tubular neighborhood of the Weyl cone $V(q(0)x, \text{st}(\tau_+))$.

It remains to show that the entry time is uniform. We will do this by backtracking, based on the fact that $V(q(0)x, \text{ost}(\tau_+))$ is an open subset of $P(\tau_-, \tau_+)$. The latter follows from the fact that $\text{ost}(\tau_+)$ is an open subset of $\partial_\infty P(\tau_-, \tau_+)$ with respect to the visual topology, see Lemma 2.9(ii).

Let \bar{p}_n denote the nearest point projection of $q(n)x$ to the parallel set $P(\tau_-, \tau_+)$. Since Γ is τ_{mod} -regular, the segment $\bar{p}_0 \bar{p}_n$ is τ_{mod} -regular for $n \geq n(\Gamma, L, A, x)$. More precisely, given $D > 0$, the distance of \bar{p}_n from $\partial V(\bar{p}_0, \text{st}(\tau_n)) = V(\bar{p}_0, \partial \text{st}(\tau_n))$ is at least D provided that $n \geq n_0(D)$, with $n_0(D)$ independent of q . We choose D sufficiently large depending on L, A, x and r (the constant r from Lemma 6.21) so that $D \gg r$ and $d(\bar{p}_n, \bar{p}_{n+1}) < D$ for all n and q . Hence the sequence \bar{p}_n cannot enter the cone $V(\bar{p}_0, \text{st}(\tau_+))$ after time $n_0(D)$, i.e. if \bar{p}_{n+1} belongs to the cone for $n \geq n_0(D)$, then \bar{p}_n itself belongs to the cone. Therefore $\bar{p}_n \in V(\bar{p}_0, \text{st}(\tau_+))$ for $n \geq n_0(D)$.

The assertion follows by suitably enlarging the uniform radius of the tubular neighborhood, e.g. by $n_0(D) \cdot D$. \square

The following is an analogue of Lemma 6.27.

Lemma 6.32. *For every (L, A) -quasigeodesic $q : \mathbb{Z} \rightarrow \Gamma$, its image qx in X is an (s, Θ) -regular discrete quasigeodesic with s , a compact subset $\Theta \subset \text{ost}(\tau_{\text{mod}})$ and the quasi-isometry constants depending on Γ, L, A, x .*

Proof. We continue the argument in the previous proof, keeping the notation.

There exists a compact Weyl convex subset $\Theta \subset \text{ost}(\tau_{\text{mod}})$ depending on Γ, L, A, x such that the segments $\bar{p}_0\bar{p}_{n_0}$ are Θ -regular for all q . This is because there are only finitely many elements $q(0)^{-1}q(n_0) \in \Gamma$. Moreover, there is a lower bound $d(\bar{p}_0, \bar{p}_{n_0}) \geq d_0 = d_0(\Gamma, L, A, x) > 0$.

We consider the nearest point projection $V(\bar{p}_0, \text{st}(\tau_+)) \rightarrow V(\bar{p}_0, \tau_+)$, which can be regarded as the restriction of the projection from $P(\tau_-, \tau_+)$ to its Euclidean de Rham factor. Let $\bar{\bar{p}}_n \in V(\bar{p}_0, \tau_+)$ denote the projection of \bar{p}_n . Since $\bar{p}_{m+n_0} \in V(\bar{p}_m, \text{st}(\tau_+))$, it follows that $\bar{\bar{p}}_{m+n_0} \in V(\bar{\bar{p}}_m, \tau_+)$. Since $\Theta \subset \text{int}(B(\xi, \frac{\pi}{2}))$ for any $\xi \in \text{int}(\tau_{\text{mod}})$ (see Lemma 2.8), we have that $d(\bar{\bar{p}}_m, \bar{\bar{p}}_{m+n_0}) \geq c(\Theta)d(\bar{p}_m, \bar{p}_{m+n_0})$ with a constant $c(\Theta) > 0$. Inductively, we obtain that $d(\bar{\bar{p}}_m, \bar{\bar{p}}_{m+kn_0}) \geq kc(\tau_{\text{mod}})c(\Theta)d_0$ for $k \in \mathbb{N}$ and some constant $c(\tau_{\text{mod}}) > 0$, compare the proof of Lemma 6.27. This establishes that qx is a uniform quasigeodesic.

The inclusion $\bar{p}_{m+n_0} \in V(\bar{p}_m, \text{st}(\tau_+))$ and the Θ -regularity of $\bar{p}_m\bar{p}_{m+n_0}$ imply that $\bar{p}_{m+n_0} \in V(\bar{p}_m, \text{st}_\Theta(\tau_+))$. Induction and the convexity of Θ -cones (Proposition 2.14) yield $\bar{p}_{m+kn_0} \in V(\bar{p}_m, \text{st}_\Theta(\tau_+))$ for all $0 < k \in \mathbb{N}$. After slightly enlarging Θ and choosing s sufficiently large (both depending on Γ, L, A, x) we obtain that qx is (s, Θ) -regular. \square

As a consequence we obtain, analogously to Theorem 6.30:

Theorem 6.33 (Coarse geometric properties of asymptotically embedded subgroups).

Let $\Gamma \subset G$ be a τ_{mod} -asymptotically embedded discrete subgroup with boundary embedding α . Suppose furthermore that Γ is non-elementary as a word hyperbolic group, $|\partial_\infty \Gamma| \geq 3$. Then:

- (i) Γ is uniformly τ_{mod} -regular.
- (ii) The orbit maps $\Gamma \rightarrow \Gamma x \subset X$ are quasi-isometric embeddings.

(iii) *The action $\Gamma \curvearrowright X$ is strongly conical in the following sense: For every $\zeta \in \partial_\infty \Gamma$ and quasiray $q : \mathbb{N} \rightarrow \Gamma$ asymptotic to ζ , the image quasiray qx lies in a uniform tubular neighborhood of the Weyl cone $V(q(0)x, \text{st}(\alpha(\zeta)))$.*

The following example shows that being undistorted without further restrictions is a very weak concept in higher rank, unlike in rank one.

Example 6.34 (Infinitely presented undistorted subgroups). Consider the group $F_2 \times F_2$ where F_2 is the free group of rank 2. Let $\phi : F_2 \rightarrow \mathbb{Z}$ be the homomorphism which sends both free generators of F_2 to the generator of \mathbb{Z} . Let $\Gamma \triangleleft F_2 \times F_2$ denote the normal subgroup

$$\Gamma = \{(h_1, h_2) : \phi(h_1) = \phi(h_2)\}.$$

Then Γ is finitely generated but Γ is not finitely presentable (see [BR]). We claim that the subgroup Γ is undistorted in $F_2 \times F_2$. Indeed, let w be a path in the Cayley graph of $F_2 \times F_2$

connecting the unit element e to an element $\gamma \in \Gamma$. We will equip \mathbb{Z} with the presentation which is the quotient of the standard presentation of $F_2 \times F_2$. Then $\phi(w)$ is a loop in \mathbb{Z} , which, therefore, bounds a van Kampen diagram D in the Cayley complex of \mathbb{Z} . Since \mathbb{Z} has a linear Dehn function, the diagram D has combinatorial area at most $C\ell(w)$, where $\ell(w)$ is the length of w (which is the same as the length of $\phi(w)$). Lifting D to the Cayley complex of $F_2 \times F_2$ results in a van Kampen diagram \tilde{D} bounding a bigon one of whose sides is w and the other is a path u in the Cayley graph of Γ . Since \tilde{D} has combinatorial area at most a constant times the combinatorial area of D , we conclude that

$$\ell(u) \leq C'\ell(w).$$

Thus, Γ is indeed undistorted in $F_2 \times F_2$.

Realizing F_2 as a convex cocompact subgroup of $\text{Isom}(\mathbb{H}^2)$, we obtain a discrete quasi-isometric embedding $F_2 \times F_2 \rightarrow \text{Isom}(X)$, $X = \mathbb{H}^2 \times \mathbb{H}^2$. Then the subgroup $\Gamma \subset \text{Isom}(X)$ is undistorted and not finitely presentable. On the other hand, since Γ is not finitely presented, there is no coarse Lipschitz retraction $X \rightarrow \Gamma x$.

Note that the group Γ in this example is not weakly regular.

Theorem 6.33, in particular part 3, can be regarded as a higher rank version of the Morse Lemma for quasigeodesics in hyperbolic spaces. We will study in section 7 quasigeodesics with such a Morse property and Morse actions, whose orbit maps send uniform quasigeodesics to Morse quasigeodesics. We will show that the class of Morse actions coincides with the class of actions having the strong asymptotic properties discussed in this section (weakly RCA, asymptotically embedded and expanding at infinity).

6.5 The Anosov condition

6.5.1 Anosov representations

A notion of Anosov representations of surface groups into $PSL(n, \mathbb{R})$ was introduced by Labourie in [La06], and generalized to a notion of (P_+, P_-) -Anosov representations $\Gamma \rightarrow G$ of word hyperbolic groups into semisimple Lie groups by Guichard and Wienhard in [GW]. The goal of this section is to review this definition of Anosov representations $\Gamma \rightarrow G$ using the language of *expanding and contracting flows* and then present a closely related and equivalent definition which avoids the language of flows.

Let Γ be a non-elementary (i.e. not virtually cyclic) word hyperbolic group with a fixed word metric d_Γ and Cayley graph C_Γ . Consider a *geodesic flow* $\hat{\Gamma}$ of Γ ; such a flow was originally constructed by Gromov [G] and then improved by Champetier [C] and Mineyev [Min], resulting in definitions with different properties. We note that the exponential convergence of asymptotic geodesic rays will not be used in our discussion; as we will see, it is also irrelevant whether the trajectories of the geodesic flow are geodesics or uniform quasigeodesics in $\hat{\Gamma}$. In particular, it will be irrelevant for us which definition of $\hat{\Gamma}$ is used. Only the following properties of $\hat{\Gamma}$ will be used in the sequel:

1. $\hat{\Gamma}$ is a proper metric space.
2. There exists a properly discontinuous isometric action $\Gamma \curvearrowright \hat{\Gamma}$.
3. There exists a Γ -equivariant quasi-isometry $\pi : \hat{\Gamma} \rightarrow \Gamma$; in particular, the fibers of π are relatively compact.
4. There exists a continuous action $\mathbb{R} \curvearrowright \hat{\Gamma}$, denoted ϕ_t and called the *geodesic flow*, whose trajectories are uniform quasigeodesics in $\hat{\Gamma}$, i.e. for each $\hat{m} \in \hat{\Gamma}$ the *flow line*

$$t \rightarrow \hat{m}_t := \phi_t(\hat{m})$$

is a uniform quasi-isometric embedding $\mathbb{R} \rightarrow \hat{\Gamma}$.

5. The flow ϕ_t commutes with the action of Γ .
6. Each $\hat{m} \in \hat{\Gamma}$ defines a uniform quasigeodesic $m : t \mapsto m_t$ in Γ by the formula:

$$m_t = \pi(\hat{m}_t)$$

The natural map

$$e = (e_-, e_+) : \hat{\Gamma} \rightarrow \partial_\infty \Gamma \times \partial_\infty \Gamma - \text{Diag}$$

assigning to \hat{m} the pair of ideal endpoints $(m_{-\infty}, m_{+\infty})$ of m is continuous and surjective. In particular, every uniform quasigeodesic in $\hat{\Gamma}$ is uniformly Hausdorff close to a flow line.

The reader can think of the elements of $\hat{\Gamma}$ as *parameterized geodesics in C_Γ , so that ϕ_t acts on geodesics via reparameterization*. This was Gromov's original viewpoint, although not the one in [Min].

We say that $\hat{m} \in \hat{\Gamma}$ is *normalized* if $\pi(\hat{m}) = 1 \in \Gamma$. Similarly, maps $q : \mathbb{Z} \rightarrow \Gamma$, and $q : \mathbb{N} \rightarrow \Gamma$ will be called *normalized* if $q(0) = 1$. It is clear that every $\hat{m} \in \hat{\Gamma}$ can be sent to a normalized element of $\hat{\Gamma}$ via the action of $m_0^{-1} \in \Gamma$.

Since trajectories of ϕ_t are uniform quasigeodesics, for each normalized $\hat{m} \in \hat{\Gamma}$ we have

$$d_\Gamma(1, m_t) \approx t \tag{6.35}$$

in the sense that

$$C_1^{-1}t - C_2 \leq d_\Gamma(1, m_t) \leq C_1 t + C_2$$

for some positive constants C_1, C_2 .

Let $F^\pm = \text{Flag}(\tau_{mod}^\pm)$ be a pair of *opposite* partial flag manifolds associated to the Lie group G , i.e. they are quotient manifolds of the form $F^\pm = G/P_\pm$, where P_\pm are opposite (up to conjugation) parabolic subgroups. The conjugacy classes of P_\pm correspond to faces τ_{mod}^\pm of the model spherical Weyl chamber σ_{mod} related by $\iota(\tau_{mod}^\pm) = \tau_{mod}^\mp$. As usual, we will regard elements of F^\pm as simplices of type τ_{mod}^\pm in the Tits boundary of X .

Define the trivial bundles

$$E^\pm = \hat{\Gamma} \times F^\pm \rightarrow \hat{\Gamma}.$$

For every representation $\rho : \Gamma \rightarrow G$, the group Γ acts on both bundles via its natural action on $\hat{\Gamma}$ and via the representation ρ on F^\pm . Put a Γ -invariant background Riemannian metric

on the fibers of these bundles, which varies continuously with respect to $\hat{m} \in \hat{\Gamma}$. We will use the notation $F_{\hat{m}}^{\pm}$ for the fiber above the point \hat{m} equipped with this Riemannian metric. Since the subspace of $\hat{\Gamma}$ consisting of normalized elements is compact, it follows that for normalized \hat{m}, \hat{m}' the identity map

$$F_{\hat{m}}^{\pm} \rightarrow F_{\hat{m}'}^{\pm}$$

is uniformly bilipschitz (with bilipschitz constant independent of \hat{m}, \hat{m}'). We will identify Γ -equivariant (continuous) sections of the bundles E^{\pm} with equivariant maps $s_{\pm} : \hat{\Gamma} \rightarrow F^{\pm}$. These sections are said to be *parallel along flow lines* if

$$s_{\pm}(\hat{m}) = s_{\pm}(\hat{m}_t)$$

for all $t \in \mathbb{R}$ and $\hat{m} \in \hat{\Gamma}$.

Definition 6.36. Parallel sections s_{\pm} are called *strongly parallel along flow lines* if for any two flow lines \hat{m}, \hat{m}' with the same ideal endpoints, we have $s_{\pm}(\hat{m}) = s_{\pm}(\hat{m}')$.

Note that this property is automatic for the geodesic flows constructed by Champetier and Mineyev since (for their flows) any two flow lines which are at finite distance from each other are actually equal. Strongly parallel sections define Γ -equivariant *boundary maps*

$$\beta_{\pm} : \partial_{\infty}\Gamma \rightarrow F^{\pm}$$

from the Gromov boundary $\partial_{\infty}\Gamma$ of the word hyperbolic group Γ by:

$$\beta_{\pm} \circ e_{\pm} = s_{\pm} \tag{6.37}$$

Lemma 6.38. β_{\pm} is continuous.

Proof. Let $(\xi_{-}^n, \xi_{+}^n) \rightarrow (\xi_{-}, \xi_{+})$ be a converging sequence in $\partial_{\infty}\Gamma \times \partial_{\infty}\Gamma - \text{Diag}$. There exists a bounded sequence (\hat{m}^n) in $\hat{\Gamma}$ so that $e_{\pm}(\hat{m}^n) = \xi_{\pm}^n$. It subconverges, $\hat{m}^n \rightarrow \hat{m}$. The continuity of s_{\pm} implies that $\beta_{\pm}(\xi_{\pm}^n) = s_{\pm}(\hat{m}^n) \rightarrow s_{\pm}(\hat{m}) = \beta_{\pm}(\xi_{\pm})$. This shows that no subsequence of $(\beta_{\pm}(\xi_{\pm}^n))$ can have a limit $\neq \beta_{\pm}(\xi_{\pm})$, and the assertion follows because F^{\pm} is compact. \square

Conversely, equivariant continuous maps β_{\pm} define Γ -equivariant sections strongly parallel along flow lines just by (6.37).

Consider the canonical “identity” maps

$$\Phi_{\hat{m}, t} : F_{\hat{m}}^{\pm} \rightarrow F_{\phi_t \hat{m}}^{\pm}$$

These maps distort the Riemannian metric on the fibers. Using Definition 2.1, we define the *expansion factor* of the flow $\phi(t)$ on the fiber $F_{\hat{m}}^{\pm}$ at the point $s_{\pm}(\hat{m})$ as

$$\epsilon_{\pm}(\hat{m}, t) := \epsilon(\Phi_{\hat{m}, t}, s_{\pm}(\hat{m})),$$

see Definition 2.1 for the definition of the expansion factor of a diffeomorphism.

Definition 6.39. The geodesic flow ϕ_t is said to be *uniformly exponentially expanding* on the bundles E^\pm with respect to the sections s_\pm if there exist constants $a, c > 0$ such that

$$\epsilon_\pm(\hat{m}, \pm t) \geq ae^{ct}$$

for all $\hat{m} \in \hat{\Gamma}$ and $t \geq 0$.

Our next goal is to give an alternative interpretation for the uniform expansion in this definition. First of all, since the metrics on the fibers are Γ -invariant, it suffices to verify uniform exponential expansion only for normalized elements of $\hat{\Gamma}$. Consider a normalized element $\hat{m} \in \hat{\Gamma}$ and for $t \in \mathbb{R}$ the composition

$$m_t^{-1} \circ \Phi_{\hat{m}, t} : F_{\hat{m}}^\pm \rightarrow F_{m_t^{-1}\hat{m}_t}^\pm.$$

Note that $\pi(m_t^{-1}\hat{m}_t) = m_t^{-1}m_t = 1$, i.e. both \hat{m} and $m_t^{-1}\hat{m}_t$ are normalized. Since the group Γ acts isometrically on the fibers of the bundles E^\pm , the metric distortion of the above compositions is exactly the same as the distortion of $\Phi_{\hat{m}, t}$. Furthermore, since, as we noted above, the metrics on $F_{\hat{m}}^\pm$ and $F_{m_t^{-1}\hat{m}_t}^\pm$ are uniformly bilipschitz to each other (via the “identity” map), the rate of expansion for the above composition is (up to a uniform multiplicative error) the same as the expansion rate for the map

$$\rho(m_t^{-1}) : F^\pm \rightarrow F^\pm.$$

(Here we are using fixed background Riemannian metrics on F^\pm .) Thus, we get the estimate

$$C_3^{-1}\epsilon(\rho(m_t^{-1}), \beta_\pm(m_{\pm\infty})) \leq \epsilon_\pm(\hat{m}, t) \leq C_3\epsilon(\rho(m_t^{-1}), \beta_\pm(m_{\pm\infty}))$$

for some uniform constant $C_3 > 1$. By taking into account the equation (6.35), we obtain the following equivalent reformulation of Definition 6.39:

Lemma 6.40. *The geodesic flow is uniformly exponentially expanding with respect to the sections s_\pm if and only if for every normalized uniform quasigeodesic $\gamma : \mathbb{Z} \rightarrow \Gamma$, which is asymptotic to points $\xi_\pm = \gamma(\pm\infty) \in \partial_\infty\Gamma$, the elements $\rho(\gamma(\pm n))^{-1}$ act on $T_{\beta_\pm(\xi_\pm)}F^\pm$ with uniform exponential expansion rate, i.e.*

$$\epsilon(\rho(\gamma(\pm n))^{-1}, \beta_\pm(\xi_\pm)) \geq Ae^{Cn}$$

for all $\hat{m} \in \hat{\Gamma}$ and $n \geq 0$ with some fixed constants $A, C > 0$.

Proof. There exists a normalized flow line \hat{m} uniformly close to γ , i.e. $\gamma(n)$ is uniformly close to m_{t_n} with $t_n \approx n$ uniformly. Then $m_{\pm\infty} = \xi_\pm$, and $\epsilon(\rho(\gamma(\pm n))^{-1}, \beta_\pm(\xi_\pm))$ equals $\epsilon(\rho(m_{t_{\pm n}}^{-1}), \beta_\pm(m_{\pm\infty}))$ up to a uniform multiplicative error, and hence also $\epsilon_\pm(\hat{m}, t_{\pm n})$. \square

Since every uniformly quasigeodesic ray $\gamma : \mathbb{N} \rightarrow \Gamma$ extends to a uniform complete quasigeodesic $\gamma : \mathbb{Z} \rightarrow \Gamma$, and in view of Morse lemma for hyperbolic groups, in the above definition it suffices to consider only normalized integer geodesic rays $\gamma : \mathbb{N} \rightarrow \Gamma$.

We can now give the original and an alternative definition of Anosov representations.

Definition 6.41. A pair of continuous maps $\beta_{\pm} : \partial_{\infty}\Gamma \rightarrow \mathbb{F}^{\pm}$ is said to be *antipodal* if it satisfies the following conditions (called *compatibility* in [GW]):

(i) For every pair of distinct ideal points $\zeta, \zeta' \in \partial_{\infty}\Gamma$, the simplices $\beta_{+}(\zeta), \beta_{-}(\zeta')$ in the Tits boundary of X are antipodal, equivalently, the corresponding parabolic subgroups of G are opposite. (In [GW] this property is called *transversality*.)

(ii) For every $\zeta \in \partial_{\infty}\Gamma$, the simplices $\beta_{+}(\zeta), \beta_{-}(\zeta)$ belong to the same spherical Weyl chamber, i.e. the intersection of the corresponding parabolic subgroups of G contains a Borel subgroup.

Note that, as a consequence, the maps β_{\pm} are *embeddings*, because antipodal simplices cannot be faces of the same chamber.

Definition 6.42 ([GW]). A representation $\rho : \Gamma \rightarrow G$ is said to be (P_{+}, P_{-}) -Anosov if there exists an antipodal pair of continuous ρ -equivariant maps $\beta_{\pm} : \partial_{\infty}\Gamma \rightarrow \mathbb{F}^{\pm}$ such that the geodesic flow on the associated bundles E^{\pm} satisfies the uniform expansion property with respect to the sections s_{\pm} associated to the maps β_{\pm} .

The pair of maps (β_{+}, β_{-}) in this definition is called *compatible* with the Anosov representation ρ . Note that a (P_{+}, P_{-}) -Anosov representation admits a unique compatible pair of maps. Indeed, the fixed points of infinite order elements $\gamma \in \Gamma$ are dense in $\partial_{\infty}\Gamma$. The maps β_{\pm} send the attractive and repulsive fixed points of γ to fixed points of $\rho(\gamma)$ with contracting and expanding differentials, and these fixed points are unique. In particular, if P_{+} is conjugate to P_{-} then $\beta_{-} = \beta_{+}$.

We note that Guichard and Wienhard in [GW] use in their definition the uniform contraction property of the reverse flow ϕ_{-t} instead of the expansion property used above, but the two are clearly equivalent. Note also that in the definition, it suffices to verify the uniform exponential expansion property only for the bundle E_{+} . We thus obtain, as a corollary of Lemma 6.40, the following alternative definition of Anosov representations:

Proposition 6.43 (Alternative definition of Anosov representations). *A representation $\rho : \Gamma \rightarrow G$ is (P_{+}, P_{-}) -Anosov if and only if there exists a pair of antipodal continuous ρ -equivariant maps $\beta_{\pm} : \partial_{\infty}\Gamma \rightarrow \mathbb{F}^{\pm}$ such that for every normalized geodesic ray (equivalently, for every uniformly quasigeodesic ray) $\gamma : \mathbb{N} \rightarrow \Gamma$ asymptotic to $\xi \in \partial_{\infty}\Gamma$, the elements $\rho(\gamma(n))^{-1}$ act on $T_{\beta_{+}(\xi)}\mathbb{F}_{+}$ with uniform exponential expansion rate, i.e.*

$$\epsilon(\rho(\gamma(n))^{-1}, \beta_{+}(\xi)) \geq Ae^{Cn} \tag{6.44}$$

for $n \geq 0$ with constants $A, C > 0$ which are independent of γ .

We now restrict to the case that the parabolic subgroups P_{\pm} are conjugate to each other, i.e. the simplices τ_{mod}^{\pm} are equal to an ι -invariant face τ_{mod} of σ_{mod} . The (P_{+}, P_{-}) -Anosov representations will in this case be called simply *P-Anosov*, where $P = P_{+}$, or τ_{mod} -Anosov. Note that the study of general (P_{+}, P_{-}) -Anosov representations quickly reduces to the case of *P-Anosov* representations by intersecting parabolic subgroups, cf. [GW, Lemma 3.18]. Now,

$$\mathbb{F}^{\pm} = \mathbb{F} = G/P = \text{Flag}(\tau_{mod})$$

and

$$\beta_{\pm} = \beta : \partial_{\infty}\Gamma \rightarrow \mathbb{F}$$

is a single continuous embedding. The compatibility condition reduces to the *antipodality* condition: For any two distinct ideal points $\zeta, \zeta' \in \partial_{\infty}\Gamma$ the simplices $\beta(\zeta)$ and $\beta(\zeta')$ are antipodal to each other. In other words, β is a *boundary embedding* in the sense of Definition 6.18.

We thus arrive to our definition:

Definition 6.45 (Anosov representation). Let P be a parabolic subgroup which is conjugate to its opposite parabolic subgroups, and let $\tau_{mod} \subset \sigma_{mod}$ the corresponding face type. We call a representation $\rho : \Gamma \rightarrow G$ *P -Anosov* or τ_{mod} -Anosov if it is τ_{mod} -boundary embedded (cf. Definition 6.18) with boundary embedding $\beta : \partial_{\infty}\Gamma \rightarrow \mathbb{F} = G/P$ such that for every normalized geodesic ray $q : \mathbb{N} \rightarrow \Gamma$ asymptotic to $\zeta \in \partial_{\infty}\Gamma$, the elements $\rho(q(n))^{-1}$ act on $T_{\beta(\zeta)}\mathbb{F}$ with uniform exponential expansion rate, i.e.

$$\epsilon(\rho(q(n))^{-1}, \beta(\zeta)) \geq Ae^{Cn}$$

for $n \geq 0$ with constants $A, C > 0$ independent of q .

We will refer to $\rho(\Gamma)$ as a τ_{mod} -Anosov subgroup of G .

6.5.2 Non-uniformly expanding Anosov representations

In this section we discuss a further weakening of the Anosov condition which leads, however, to the same class of group actions. We restrict our discussion to the case of ι -invariant model simplices $\tau_{mod} \subset \sigma_{mod}$ and the corresponding parabolic subgroups $P \subset G$ (conjugate to their opposites), even though, with minor modifications, the same proofs go through for arbitrary pairs of opposite (up to conjugation) parabolic subgroups $P_{\pm} \subset G$.

We note that in the definition of Anosov representation (both the original definition and the alternative one) the constants a and c (respectively, A and C) were required to be uniform for the entire group. The main goal of this section is to show that the requirement of uniform exponential expansion can be relaxed and that the weakened notion is still equivalent to the Anosov condition as well as to the concept of asymptotic embedding for discrete subgroups.

Definition 6.46 (Non-uniformly Anosov representation). We call a representation $\rho : \Gamma \rightarrow G$ of a word hyperbolic group Γ *non-uniformly τ_{mod} -Anosov* if it is τ_{mod} -boundary embedded with boundary embedding $\beta : \partial_{\infty}\Gamma \rightarrow \text{Flag}(\tau_{mod})$ such that for every normalized discrete geodesic ray (equivalently, normalized uniform quasiray) $q : \mathbb{N} \rightarrow \Gamma$ asymptotic to $\zeta \in \partial_{\infty}\Gamma$, the elements $\rho(q(n))^{-1}$ act on $T_{\beta(\zeta)}\mathbb{F}$ with unbounded expansion rate:

$$\sup_{n \geq 0} \epsilon(\rho(q(n))^{-1}, \beta(\zeta)) = +\infty. \tag{6.47}$$

Note that this definition does not even have the requirement that the expansion rate of $\rho(q(n))^{-1}$ at τ diverges to infinity. Other weakenings of the Anosov condition appear in [La06,

sec. 6.1] and [GW, Prop. 3.16]. They assume uniform, not necessarily exponential, divergence to infinity of the expansion factors along the trajectories of the geodesic flow.

Non-uniformly Anosov representations clearly have finite kernel (and discrete image). Therefore we will consider from now on only the case when Γ is a subgroup of G .

Theorem 6.48 (Non-uniformly Anosov implies asymptotically embedded). *Every non-uniformly τ_{mod} -Anosov subgroup is τ_{mod} -asymptotically embedded.*

Proof. We first establish a weak form of continuity at infinity and conicality for the boundary embedding of a non-uniformly Anosov subgroups:

Lemma 6.49. *Suppose that $\Gamma \subset G$ is non-uniformly τ_{mod} -Anosov with boundary embedding β . Then for every discrete geodesic ray $q : \mathbb{N} \rightarrow \Gamma$, the sequence $(q(n))$ in Γ contains a τ_{mod} -regular subsequence $(q(n_i))$ such that $q(n_i) \xrightarrow{f} \beta(q(+\infty))$ conically. In particular, $\beta(\partial_\infty \Gamma) \subset \Lambda_{\tau_{mod}}(\Gamma)$.*

Proof. We fix a point $x \in X$. Since by definition, Γ is τ_{mod} -boundary embedded, the discussion in section 6.4.1 applies. By Lemma 6.21, the image under the orbit map $\Gamma \rightarrow \Gamma x \subset X$ of every discrete geodesic $q : \mathbb{Z} \rightarrow \Gamma$ is uniformly close to the parallel set $P(\beta(q(-\infty)), \beta(q(+\infty)))$, i.e. there is a constant $r > 0$ independent of q such that

$$d(q(n), P(\beta(q(-\infty)), \beta(q(+\infty)))) < r \quad (6.50)$$

for all q and $n \in \mathbb{Z}$.

We will now establish a weak analogue of Lemma 6.31, taking into account the infinitesimal expansion property (6.47). To make use of the expansion property, we need a version, in particular, a converse of Lemma 6.9 for sequences close to parallel sets and their infinitesimal contraction at infinity:

Sublemma 6.51. *Let (g_n) be a sequence in G whose orbit sequence $(g_n x)$ for a point $x \in X$ is contained in a tubular neighborhood of the parallel set $P(\tau_-, \tau_+)$. Then the following are equivalent:*

- (i) *The sequence (g_n) is τ_{mod} -regular and $g_n \xrightarrow{f} \tau_+$ conically.*
- (ii) *The differentials $(dg_n^{-1})_{\tau_+}$ expand arbitrarily strongly, i.e.*

$$\lim_{n \rightarrow +\infty} \epsilon(g_n^{-1}, \tau_+) = +\infty \quad (6.52)$$

with respect to a fixed background metric on $\text{Flag}(\tau_{mod})$.

Proof. We proceed as in the proof of Corollary 2.55. Let $\bar{x} \in P(\tau_-, \tau_+)$ denote the nearest point projection of x . We write the g_n as products $g_n = t_n b_n$ of transvections $t_n \in G$ along geodesics $l_n \subset P(\tau_-, \tau_+)$ through \bar{x} and bounded isometries $b_n \in G$, e.g. such that $d(b_n \bar{x}, \bar{x}) < 2r$. Then the t_n fix τ_+ on $\text{Flag}(\tau_{mod})$, and the expansion factors $\epsilon(g_n^{-1}, \tau_+)$ are the same as $\epsilon(t_n^{-1}, \tau_+)$ up to bounded multiplicative error. In view of $\epsilon(t_n^{-1}, \tau_+) = \|(dt_n)_{\tau_+}\|^{-1}$, condition (6.52) translates to the infinitesimal contraction condition

$$\lim_{n \rightarrow +\infty} \|(dt_n)_{\tau_+}\| = 0.$$

According to Theorem 2.54, the latter is equivalent to $t_n \bar{x}$ being contained in $V(\bar{x}, \text{st}(\tau_+))$ for large n and

$$\lim_{n \rightarrow +\infty} d(t_n \bar{x}, \partial V(\bar{x}, \text{st}(\tau_+))) = \lim_{n \rightarrow +\infty} d(t_n^{-1} \bar{x}, \partial V(\bar{x}, \text{st}(\tau_-))) = +\infty.$$

Since $d(g_n \bar{x}, t_n \bar{x}) = d(b_n \bar{x}, \bar{x})$ is bounded, this is in turn equivalent to (g_n) being τ_{mod} -regular and the constant sequence (τ_+) being a shadow of (g_n) in $\text{Flag}(\tau_{mod})$, i.e. $g_n \xrightarrow{f} \tau_+$ conically. \square

The lemma follows by applying the sublemma to q . Since Γ is word hyperbolic, every discrete geodesic ray $\mathbb{N} \rightarrow \Gamma$ is contained in a uniform tubular neighborhood of a discrete geodesic $\mathbb{Z} \rightarrow \Gamma$. So, we may assume that q extends to a discrete geodesic $q : \mathbb{Z} \rightarrow \Gamma$ and, moreover, that it is normalized. Since

$$\lim_{i \rightarrow +\infty} \epsilon(q(n_i)^{-1}, \beta(q(+\infty))) = +\infty$$

for some sequence of indices $n_i \rightarrow +\infty$ in \mathbb{N} by property (6.47), the sublemma yields that the subsequence $(q(n_i))_{i \in \mathbb{N}}$ is τ_{mod} -regular and $q(n_i) \xrightarrow{f} \beta(q(+\infty))$ conically as $i \rightarrow +\infty$. \square

At this stage we do not yet know that the entire subgroup Γ is τ_{mod} -regular, nor do we know that $\beta(\partial_\infty \Gamma) = \Lambda_{\tau_{mod}}(\Gamma)$. The problem is that we have no uniform control yet on the distance of $q(n)x$ from the Weyl cone $V(q(0)x, \text{st}(\beta(q(+\infty))))$. This will be our next aim.

In the sequel, we will denote the nearest point projections of points y in X to the parallel set $P(\beta(q(-\infty)), \beta(q(+\infty)))$ by \bar{y} .

The proof of Sublemma 6.51 yields the following additional information. Since $d(g_n x, t_n \bar{x}) \leq d(g_n x, g_n \bar{x}) + d(g_n \bar{x}, t_n \bar{x}) < 3r$, it follows (for unnormalized q) that

$$\overline{q(n_i)x} \in V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$$

for all i , and

$$\lim_{i \rightarrow +\infty} d(\overline{q(n_i)x}, \partial V(\overline{q(0)x}, \text{st}(\beta(q(+\infty)))))) = +\infty$$

We fix a constant $d \gg 0$ and define for a discrete geodesic $q : \mathbb{Z} \rightarrow \Gamma$ the *entry time* $T(q) \in \mathbb{N}$ as the smallest natural number ≥ 1 for which

$$\overline{q(T)x} \in V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$$

and

$$d(\overline{q(T)x}, \partial V(\overline{q(0)x}, \text{st}(\beta(q(+\infty)))))) > d.$$

Lemma 6.53 (Bounded entry time). *$T(q)$ is bounded above independently of q .*

Proof. We first observe that the function T on the space $\mathcal{G}(\Gamma)$ of discrete geodesics in Γ , equipped with the topology of pointwise convergence, is upper semicontinuous, because β is continuous. Since T is Γ -periodic and the Γ -action on $\mathcal{G}(\Gamma)$ is cocompact, the claim follows. \square

Now we can strengthen Lemma 6.49 and show that the orbit maps of rays in Γ stay uniformly close to the Weyl cones associated to them by the boundary embedding, and that their nearest point projections to these Weyl cones move away from the boundaries of the cones at a uniform linear rate:

Lemma 6.54. (i) *The distance of $q(n)x$ from the Weyl cone $V(q(0)x, \text{st}(\beta(q(+\infty))))$ is uniformly bounded for all $n \geq 0$ independently of q .*

(ii) *The distance of $q(n)x$ from the boundary*

$$\partial V(q(0)x, \text{st}(\beta(q(+\infty))))$$

of the Weyl cone is at least $Cn - A$ for all $n \geq 0$ with constants $C, A > 0$ independent of q .

Proof. We inductively define a sequence of i -th entry times $T_i(q)$ for $i \geq 0$ by $T_0(q) := 0$ and

$$T_{i+1}(q) - T_i(q) := T(q_i)$$

for $i \geq 1$, where $T(q_i)$ is the entry time of the shifted discrete geodesic $q_i(n) = q(T_i(q) + n)$ with the same ideal endpoints. Then $T(q_i)$ and the increments $T_{i+1}(q) - T_i(q)$ are bounded above independently of q , and $T_i(q) \rightarrow +\infty$ monotonically as $i \rightarrow +\infty$, because $T \geq 1$. By taking into account that $q(\pm\infty) = q_i(\pm\infty)$, the definition of the $T(q_i)$ implies:

$$\overline{q(T_{i+1})x} \in V(\overline{q(T_i)x}, \text{st}(\beta(q(+\infty)))) - N_d(\partial V(\overline{q(T_i)x}, \text{st}(\beta(q(+\infty))))))$$

Corollary 2.19 yields that the cones are nested,

$$V(\overline{q(T_{i+1})x}, \text{st}(\beta(q(+\infty)))) \subset V(\overline{q(T_i)x}, \text{st}(\beta(q(+\infty))))),$$

and it hence follows that

$$d(\overline{q(T_i)x}, \partial V(\overline{q(0)x}, \text{st}(\beta(q(+\infty)))))) > id.$$

Note that T_i grows uniformly linearly with i , i.e.

$$c^{-1}i \leq T_i \leq ci$$

for $i \geq 1$ with a constant $c \geq 1$ independent of q . Moreover, the increments $T_{i+1} - T_i$ are uniformly bounded. These two observations imply that:

(i) The distance of $\overline{q(n)x}$ from $V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$ is uniformly bounded for all $n \geq 0$ independently of q ; and

(ii) the distance of $\overline{q(n)x}$ from the complement

$$P(\beta(q(-\infty)), \beta(q(+\infty))) - V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$$

is $\geq Cn - A$ for all $n \geq 0$ with constants $C, A > 0$ independent of q .

The claim follows, because the Hausdorff distance between the cones $V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$ and $V(\overline{q(0)x}, \text{st}(\beta(q(+\infty))))$ is $\leq d(q(0)x, \overline{q(0)x}) < r$, as well as $d(q(n)x, \overline{q(n)x}) < r$. \square

It follows that the group Γ is uniformly τ_{mod} -regular.

We will finally deduce from the last lemma that $\beta(\partial_\infty \Gamma) = \Lambda_{\tau_{mod}}(\Gamma)$, i.e. that β maps *onto* the τ_{mod} -limit set. We proceed as in the proof of Proposition 6.24.

Suppose that $\tau \in \Lambda_{\tau_{mod}}(\Gamma)$ and let (γ_n) be a sequence in Γ with

$$\gamma_n \xrightarrow{f} \tau. \quad (6.55)$$

Since Γ is word hyperbolic, there exists a sequence of discrete geodesic rays $q_n : \mathbb{N} \rightarrow \Gamma$ initiating in $q_n(0) = 1_\Gamma$ and passing at uniformly bounded distance from γ_n , i.e. $(q_n(+\infty))$ is a shadow sequence for (γ_n) in $\partial_\infty \Gamma$. After passing to a subsequence, the q_n converge (pointwise) to a ray $q : \mathbb{N} \rightarrow \Gamma$. Then $q_n(+\infty) \rightarrow q(+\infty)$ and

$$\beta(q_n(+\infty)) \rightarrow \beta(q(+\infty)). \quad (6.56)$$

As a consequence of Lemma 6.54, $(\beta(q_n(+\infty)))$ is a shadow sequence for (γ_n) in $\text{Flag}(\tau_{mod})$. Therefore, (6.55) and (6.56) imply that $\beta(q_n(+\infty)) \xrightarrow{f} \tau$, cf. Lemma 5.15. Hence $\beta(q(+\infty)) = \tau$, i.e. τ is in the image of β . \square

Thus, Γ is τ_{mod} -asymptotically embedded. This concludes the proof of Theorem 6.48. \square

We are now ready to prove the equivalence of three concepts, namely of the (non-uniformly) Anosov property and asymptotic embeddedness. Note that equivalences of the Anosov condition with other weakened forms of it appear in [La06, sec. 6.1] and [GW, Prop. 3.16].

Theorem 6.57. *For a discrete subgroup $\Gamma \subset G$ which is non-elementary word hyperbolic, the following are equivalent:*

1. Γ is τ_{mod} -Anosov.
2. Γ is non-uniformly τ_{mod} -Anosov.
3. Γ is τ_{mod} -asymptotically embedded.

Proof. The implication $1 \Rightarrow 2$ is immediate; implication $2 \Rightarrow 3$ is established in Theorem 6.48. It remains to prove that $3 \Rightarrow 1$.

Suppose that $\Gamma \subset G$ is τ_{mod} -asymptotically embedded with boundary embedding β . We use our results on the coarse geometry of asymptotically embedded subgroups, see Theorem 6.33. For a discrete geodesic ray $q : \mathbb{N} \rightarrow \Gamma$ we know that its image $qx : \mathbb{N} \rightarrow X$ is a uniformly τ_{mod} -regular discrete quasigeodesic ray uniformly close to the Weyl cone $V(q(0)x, \text{st}(\beta(q(+\infty))))$. In particular, it moves away from the boundary $\partial V(q(0)x, \text{st}(\beta(q(+\infty))))$ of the cone with uniform linear speed. Therefore, Corollary 2.55 yields that the elements $q(n)^{-1}$ have uniform exponential expansion rate at $\beta(q(+\infty)) \in \text{Flag}(\tau_{mod})$,

$$\epsilon(q(n)^{-1}, \beta(q(+\infty))) \geq Ae^{Cn},$$

with constants $A, C > 0$ independent of q . Hence, the subgroup $\Gamma \subset G$ is τ_{mod} -Anosov. \square

As a corollary we obtain:

Corollary 6.58. *Let Γ be a non-elementary word hyperbolic group. An isometric action $\rho : \Gamma \curvearrowright X$ is τ_{mod} -Anosov if and only if the kernel of ρ is finite and $\rho(\Gamma) \subset G$ is a τ_{mod} -asymptotically embedded discrete subgroup.*

7 Morse maps and actions

In section 6.4.3 we saw that asymptotically embedded subgroups satisfy an important coarse geometric property, namely the orbit maps sends uniform quasigeodesic rays in Γ to quasigeodesic rays $x_n = q(n)x$ in X which stay within bounded distance from Weyl cones. We also saw that this property has important consequences: nondistortion of Γ and uniform weak regularity. We will call this property of sequences (x_n) the *Morse property*. The corresponding class of group actions will be called *Morse actions*. It is not hard to verify that, conversely, Morse actions satisfy asymptotic embeddedness.

In this section we further investigate the Morse property of sequences and group actions. The main aim of this section is to establish a local criterion for being Morse. To do so we introduce a local notion of *straightness* for sequences of points in X . Morse sequences are in general not straight, but they become straight after suitable modification, namely by sufficiently coarsifying them and then passing to the sequence of successive midpoints. Conversely, the key result is that sufficiently spaced straight sequences are Morse. We conclude that there is a local-to-global implication for the Morse property.

As a consequence of the local-to-global criterion we establish that the Morse property for isometric group actions is an open condition. Furthermore, for two nearby Morse actions, the actions on their τ_{mod} -limit sets are also close, i.e. conjugate by an equivariant homeomorphism close to identity. In view of the equivalence of Morse property with the asymptotic properties discussed earlier, this implies structural stability for asymptotically embedded groups. Another corollary of the local-to-global result is the algorithmic recognizability of Morse actions.

We conclude the section by illustrating our technique by constructing Morse-Schottky actions of free groups on higher rank symmetric spaces. Unlike all previously known constructions, our proof does not rely on ping-pong, but is purely geometric and proceeds by constructing equivariant quasi-isometric embeddings of trees.

For the rest of this section we fix the following notation and conventions:

Let $\tau_{mod} \subseteq \sigma_{mod}$ be an ι -invariant face type.

We fix as auxiliary datum a ι -invariant type $\zeta = \zeta_{mod} \in \text{int}(\tau_{mod})$. (We will omit the subscript in ζ_{mod} in order to avoid cumbersome notation for ζ -angles.) This allows us to define the ζ -angle \angle^ζ and ζ -Tits angle \angle_{Tits}^ζ , see equations (2.3) and (2.4). For a simplex $\tau \subset \partial_\infty X$ of type τ_{mod} we define $\zeta(\tau) \in \tau$ as the ideal point of type ζ_{mod} . For a τ_{mod} -regular unit tangent vector $v \in TX$ we denote by $\tau(v) \subset \partial_\infty X$ the unique simplex of type τ_{mod} such that ray ρ_v with initial direction v represents an ideal point in $\text{ost}(\tau(v))$. We put $\zeta(v) = \zeta(\tau(v))$. Note that $\zeta(v)$ depends continuously on v .

In this section $\Theta, \Theta' \subset \text{ost}(\tau_{mod})$ will denote ι -invariant τ_{mod} -convex compact subsets such that $\Theta \subset \text{int}(\Theta')$. The constants $L, A, D, \epsilon, \delta, l, a, s, S$ are meant to be always strictly positive.

7.1 A Morse Lemma for straight sequences

In the following, we consider finite or infinite sequences (x_n) of points in X .

Definition 7.1 (Straight and spaced sequence). We call a sequence (x_n) (Θ, ϵ) -straight if the segments $x_n x_{n+1}$ are Θ -regular and

$$\angle_{x_n}^{\zeta}(x_{n-1}, x_{n+1}) \geq \pi - \epsilon$$

for all n . We call it l -spaced if the segments $x_n x_{n+1}$ have length $\geq l$.

Note that every straight sequence can be extended to a biinfinite straight sequence.

Straightness is a local condition. The goal of this section is to prove the following local to global result asserting that sufficiently straight and spaced sequences satisfy a higher rank version of the Morse Lemma (for quasigeodesics in hyperbolic space).

Theorem 7.2 (Morse Lemma for straight spaced sequences). For Θ, Θ', δ there exist l, ϵ such that:

Every (Θ, ϵ) -straight l -spaced sequence (x_n) is δ -close to a parallel set $P(\tau_-, \tau_+)$ with simplices τ_{\pm} of type τ_{mod} , and it moves from τ_- to τ_+ in the sense that its nearest point projection \bar{x}_n to $P(\tau_-, \tau_+)$ satisfies

$$\bar{x}_{n \pm m} \in V(\bar{x}_n, \text{st}_{\Theta'}(\tau_{\pm})) \quad (7.3)$$

for all n and $m \geq 1$.

Remark 7.4 (Global spacing). 1. As a corollary of this theorem, we will show that straight spaced sequences are quasigeodesic:

$$d(x_n, x_{n+m}) \geq cm - 2\delta$$

with a constant $c = c(\Theta') > 0$. See Corollary 7.13.

2. Theorem 7.2 is a higher-rank generalization of two familiar facts from geometry of Gromov-hyperbolic geodesic metric spaces: The fact that local quasigeodesics (with suitable parameters) are global quasigeodesics and the Morse lemma stating that quasigeodesics stay uniformly close to geodesics. In the higher rank, quasigeodesics, of course, need not be close to geodesics, but, instead (under the straightness assumption), are close to parallel sets.

In order to prove the theorem, we start by considering one-sided infinite sequences and prove that they keep moving away from an ideal simplex of type τ_{mod} if they do so initially.

Definition 7.5 (Moving away from an ideal simplex). Given a face $\tau \subset \partial_{Tits} X$ of type τ_{mod} and distinct points $x, y \in X$, define the angle

$$\angle_x^{\zeta}(\tau, y) := \angle_x(z, y)$$

where z is a point (distinct from x) on the geodesic ray $x\xi$, where $\xi \in \tau$ is the point of type ζ .

We say that a sequence (x_n) moves ϵ -away from a simplex τ of type τ_{mod} if

$$\angle_{x_n}^\zeta(\tau, x_{n+1}) \geq \pi - \epsilon$$

for all n .

Lemma 7.6 (Moving away from ideal simplices). *For small ϵ and large l , $\epsilon \leq \epsilon_0$ and $l \geq l(\epsilon, \Theta)$, the following holds:*

If the sequence $(x_n)_{n \geq 0}$ is (Θ, ϵ) -straight l -spaced and if

$$\angle_{x_0}^\zeta(\tau, x_1) \geq \pi - 2\epsilon,$$

then (x_n) moves ϵ -away from τ .

Proof. By Lemma 2.44(ii), the unit speed geodesic segment $c : [0, t_1] \rightarrow X$ from $p(0)$ to $p(1)$ moves $\epsilon(d(2\epsilon))$ -away from τ at all times, and $\epsilon'(2\epsilon, \Theta, l)$ -away at times $\geq l$, which includes the final time t_1 . For $l(\epsilon, \Theta)$ sufficiently large, we have $\epsilon'(2\epsilon, \Theta, l) \leq \epsilon$. Then c moves ϵ -away from τ at time t_1 , which means that $\angle_{x_1}^\zeta(\tau, x_0) \leq \epsilon$. Straightness at x_1 and the triangle inequality yield that again $\angle_{x_1}^\zeta(\tau, x_2) \geq \pi - 2\epsilon$. One proceeds by induction. \square

Note that there do exist simplices τ satisfying the hypothesis of the previous lemma. For instance, one can extend the initial segment x_0x_1 backwards to infinity and choose $\tau = \tau(x_1x_0)$.

Now we look at *biinfinite* sequences.

We assume in the following that $(x_n)_{n \in \mathbb{Z}}$ is (Θ, ϵ) -straight l -spaced for small ϵ and large l . As a first step, we study the asymptotics of such sequences and use the argument for Lemma 7.6 to find a pair of opposite ideal simplices τ_\pm such that (x_n) moves from τ_- towards τ_+ .

Lemma 7.7 (Moving towards ideal simplices). *For small ϵ and large l , $\epsilon \leq \epsilon_0$ and $l \geq l(\epsilon, \Theta)$, the following holds:*

There exists a pair of opposite simplices τ_\pm of type τ_{mod} such that the inequality

$$\angle_{x_n}^\zeta(\tau_\mp, x_{n \pm 1}) \geq \pi - 2\epsilon \tag{7.8}$$

holds for all n .

Proof. 1. For every n define a compact set $C_n^\mp \subset \text{Flag}(\tau_{mod})$

$$C_n^\pm = \{\tau_\pm : \angle_{x_n}^\zeta(\tau_\pm, x_{n \mp 1}) \geq \pi - 2\epsilon\}.$$

As in the proof of Lemma 7.6, straightness at x_{n+1} implies that $C_n^- \subset C_{n+1}^-$. Hence the family $\{C_n^-\}_{n \in \mathbb{Z}}$ form a nested sequence of nonempty compact subsets and therefore have nonempty intersection containing a simplex τ_- . Analogously, there exists a simplex τ_+ which belongs to C_n^+ for all n .

2. It remains to show that the simplices τ_-, τ_+ are antipodal. Using straightness and the triangle inequality, we see that

$$\angle_{x_n}^\zeta(\tau_-, \tau_+) \geq \pi - 5\epsilon$$

for all n . Hence, if $5\epsilon < \epsilon(\zeta)$, then the simplices τ_-, τ_+ are antipodal in view of Remark 2.42. \square

The pair of opposite simplices (τ_-, τ_+) which we found determines a parallel set in X . The second step is to show that (x_n) is uniformly close to it.

Lemma 7.9 (Close to parallel set). *For small ϵ and large l , $\epsilon \leq \epsilon(\delta)$ and $l \geq l(\Theta, \delta)$, the sequence (x_n) is δ -close to $P(\tau_-, \tau_+)$.*

Proof. The statement follows from the combination of the inequality (7.1) (in the second part of the proof of Lemma 7.7) and Lemma 2.43. \square

The third and final step is to show that the nearest point projection (\bar{x}_n) of (x_n) to $P(\tau_-, \tau_+)$ moves from τ_- towards τ_+ .

Lemma 7.10 (Projection moves towards ideal simplices). *For small ϵ and large l , $\epsilon \leq \epsilon_0$ and $l \geq l(\epsilon, \Theta, \Theta')$, the segments $\bar{x}_n \bar{x}_{n+1}$ are Θ' -regular and*

$$\angle_{\bar{x}_n}^{\zeta}(\tau_-, \bar{x}_{n+1}) = \pi$$

for all n .

Proof. By the previous lemma, (x_n) is δ_0 -close to $P(\tau_-, \tau_+)$ if ϵ_0 is sufficiently small and l is sufficiently large. Since $x_n x_{n+1}$ is Θ -regular, the triangle inequality for Δ -lengths yields that the segment $\bar{x}_n \bar{x}_{n+1}$ is Θ' -regular, again if l is sufficiently large.

Let ξ_+ denote the ideal endpoint of the ray extending this segment, i.e. $\bar{x}_{n+1} \in \bar{x}_n \xi_+$. Then x_{n+1} is $2\delta_0$ -close to the ray $x_n \xi_+$. We obtain that

$$\angle_{Tits}^{\zeta}(\tau_-, \xi_+) \geq \angle_{x_n}^{\zeta}(\tau_-, \xi_+) \simeq \angle_{x_n}^{\zeta}(\tau_-, x_{n+1}) \simeq \pi$$

where the last step follows from inequality (7.8). The discreteness of Tits distances between ideal points of fixed type ζ implies that in fact

$$\angle_{Tits}^{\zeta}(\tau_-, \xi_+) = \pi,$$

i.e. the ideal points $\zeta(\tau_-)$ and $\zeta(\xi_+)$ are antipodal. But the only simplex opposite to τ_- in $\partial_{\infty} P(\tau_-, \tau_+)$ is τ_+ , so $\tau(\xi_+) = \tau_+$ and

$$\angle_{\bar{x}_n}^{\zeta}(\tau_-, \bar{x}_{n+1}) = \angle_{\bar{x}_n}^{\zeta}(\tau_-, \xi_+) = \pi,$$

as claimed. \square

Proof of Theorem 7.2. It suffices to consider biinfinite sequences.

The conclusion of Lemma 7.10 is equivalent to $\bar{x}_{n+1} \in V(\bar{x}_n, \text{st}_{\Theta'}(\tau_+))$. Combining Lemmas 7.9 and 7.10, we thus obtain the theorem for $m = 1$.

The convexity of Θ' -cones, cf. Proposition 2.18, implies that

$$V(\bar{x}_{n+1}, \text{st}_{\Theta'}(\tau_+)) \subset V(\bar{x}_n, \text{st}_{\Theta'}(\tau_+)),$$

and the assertion follows for all $m \geq 1$ by induction. \square

Remark 7.11. The conclusion of the theorem implies that $x_{\pm n} \xrightarrow{f} \tau_{\pm}$ as $n \rightarrow +\infty$. However, the x_n do in general not converge at infinity, but accumulate at a compact subset of $\text{st}_{\Theta'}(\tau_{\pm})$.

7.2 Lipschitz retractions

Consider a (possibly infinite) closed interval J in \mathbb{R} ; we will assume that J has integer or infinite bounds. Suppose that $p : J \cap \mathbb{Z} \rightarrow P = P(\tau_-, \tau_+) \subset X$ is an l -separated, λ -Lipschitz, $(\Theta, 0)$ -straight coarse sequence pointing away from τ_- and towards τ_+ . We extend p to a piecewise-geodesic map $p : J \rightarrow P$ by sending intervals $[n, n + 1]$ to geodesic segments $p(n)p(n + 1)$ via affine maps. We retain the name p for the extension.

Lemma 7.12. *There exists $L = L(l, \lambda, \Theta)$ and an L -Lipschitz retraction of X to p , i.e., an L -Lipschitz map $r : X \rightarrow J$ so that $r \circ p = Id$. In particular, $p : J \cap \mathbb{Z} \rightarrow X$ is a (\bar{L}, \bar{A}) -quasigeodesic, where \bar{L}, \bar{A} depend only on l, λ, Θ .*

Proof. It suffices to prove existence of a retraction. Since P is convex in X , it suffices to construct a map $P \rightarrow J$. Pick a generic point $\xi = \xi_+ \in \tau_+$ and let $b_\xi : P \rightarrow \mathbb{R}$ denote the Busemann function normalized so that $b_\xi(p(z)) = 0$ for some $z \in J \cap \mathbb{Z}$. Then the Θ -regularity assumption on p implies that the slope of the piecewise-linear function $b_\xi \circ p : J \rightarrow \mathbb{R}$ is strictly positive, bounded away from 0. The assumption that p is l -separated λ -Lipschitz implies that

$$l \leq |p'(t)| \leq \lambda$$

for each t (where the derivative exists). The straightness assumption on p implies that the function $h := b_\xi \circ p : J \rightarrow \mathbb{R}$ is strictly increasing. By combining these observations, we conclude that h is an L -biLipschitz homeomorphism for some $L = L(l, \lambda, \Theta)$. Lastly, we define

$$r : P \rightarrow J, \quad r = h^{-1} \circ b_\xi.$$

Since b_ξ is 1-Lipschitz, the map r is L -Lipschitz. By construction, $r \circ p = Id$. \square

Corollary 7.13. *Suppose that $p : J \cap \mathbb{Z} \rightarrow X$ is a l -separated, λ -Lipschitz, (Θ, ϵ) -regular straight coarse sequence. Pick some Θ' such that $\Theta \subset \text{int}(\Theta')$ and let $\delta = \delta(l, \Theta, \Theta', \epsilon)$ be the constant as in Theorem 7.2. Then for $L = L(l - 2\delta, \lambda + 2\delta, \Theta')$ we have:*

1. *There exists an $(L, 2\delta)$ -coarse Lipschitz retraction $X \rightarrow J$.*
2. *The map p is an (L', A') -quasigeodesic for L', A' depending only on $l, \Theta, \Theta', \epsilon$.*

Proof. The statement immediately follows the above lemma combined with Theorem 7.2. \square

7.3 Morse quasigeodesics

According to Theorem 7.2, sufficiently spaced straight sequences satisfy a Morse Lemma. If the spacing is also bounded above, then these sequences are quasigeodesics (Corollary 7.13). This motivates considering quasigeodesics which satisfy a higher rank version of the Morse Lemma as it appears in the conclusion of Theorem 7.2.

Definition 7.14 (Morse quasigeodesic). An (L, A, Θ, D) -Morse quasigeodesic in X is an (L, A) -quasigeodesic $p : I \rightarrow X$ such that for all $t_1, t_2 \in I$ the subpath $p|_{[t_1, t_2]}$ is D -close to a Θ -diamond $\diamond_\Theta(x_1, x_2)$ with $d(x_i, p(t_i)) \leq D$.

Note that each quasigeodesic satisfying Theorem 7.2 is Morse; the converse is also true as we will see in Lemma 7.19.

We will now prove that, conversely, the Morse property implies straightness in a suitable sense, namely that for sufficiently spaced quadruples the associated midpoint triples are arbitrarily straight. (For the quadruples themselves this is in general not true.)

Definition 7.15 (Quadruple condition). For points $x, y \in X$ we let $\text{mid}(x, y)$ denote the midpoint of the geodesic segment xy . A map $p : I \rightarrow X$ satisfies the (Θ, ϵ, l, s) -quadruple condition if for all $t_1, t_2, t_3, t_4 \in I$ with $t_2 - t_1, t_3 - t_2, t_4 - t_3 \geq s$ the triple of midpoints

$$(\text{mid}(t_1, t_2), \text{mid}(t_2, t_3), \text{mid}(t_3, t_4))$$

is (Θ, ϵ) -straight and l -spaced.

Proposition 7.16 (Morse implies quadruple condition). For $L, A, \Theta, \Theta', D, \epsilon, l$ exists a scale $s = s(L, A, \Theta, \Theta', D, \epsilon, l)$ such that every (L, A, Θ, D) -Morse quasigeodesic satisfies the $(\Theta', \epsilon, l, s')$ -quadruple condition for every $s' \geq s$.

Proof. Let $p : I \rightarrow X$ be an (L, A, Θ, D) -Morse quasigeodesic, and let $t_1, \dots, t_4 \in I$ such that $t_2 - t_1, t_3 - t_2, t_4 - t_3 \geq s$. We abbreviate $p_i := p(t_i)$ and $m_i = \text{mid}(p_i, p_{i+1})$.

Regarding straightness, it suffices to show that the segment $m_2 m_1$ is Θ' -regular and that $\angle_{m_2}^{\zeta}(p_2, m_1) \leq \frac{\epsilon}{2}$ provided that s is sufficiently large in terms of the given data.

By the Morse property, there exists a diamond $\diamond_{\Theta}(x_1, x_3)$ such that $d(x_1, p_1), d(x_3, p_3) \leq D$ and $p_2 \in N_D(\diamond_{\Theta}(x_1, x_3))$. The diamond spans a unique parallel set $P(\tau_-, \tau_+)$. (Necessarily, $x_3 \in V(x_1, \text{st}_{\Theta}(\tau_+))$ and $x_1 \in V(x_3, \text{st}_{\Theta}(\tau_-))$.)

We denote by \bar{p}_i and \bar{m}_i the projections of p_i and m_i to the parallel set.

We first observe that m_2 (and m_3) is arbitrarily close to the parallel set if s is large enough. If this were not true, a limiting argument would produce a geodesic line at strictly positive finite Hausdorff distance $\in (0, D]$ from $P(\tau_-, \tau_+)$ and asymptotic to ideal points in $\text{st}_{\Theta}(\tau_{\pm})$. However, all lines asymptotic to ideal points in $\text{st}_{\Theta}(\tau_{\pm})$ are contained in $P(\tau_-, \tau_+)$.

Next, we look at the directions of the segments $\bar{m}_2 \bar{m}_1$ and $\bar{m}_2 \bar{p}_2$ and show that they have the same τ -direction. Since \bar{p}_2 is $2D$ -close to $V(\bar{p}_1, \text{st}_{\Theta}(\tau_+))$, we have that the point \bar{p}_1 is $2D$ -close to $V(\bar{p}_2, \text{st}_{\Theta}(\tau_-))$, and hence also \bar{m}_1 is $2D$ -close to $V(\bar{p}_2, \text{st}_{\Theta}(\tau_-))$. Therefore, $\bar{p}_1, \bar{m}_1 \in V(\bar{p}_2, \text{st}_{\Theta'}(\tau_-))$ if s is large enough. Similarly, $\bar{m}_2 \in V(\bar{p}_2, \text{st}_{\Theta'}(\tau_+))$ and hence $\bar{p}_2 \in V(\bar{m}_2, \text{st}_{\Theta'}(\tau_-))$. The convexity of Θ' -cones, see Proposition 2.18, implies that also $\bar{m}_1 \in V(\bar{m}_2, \text{st}_{\Theta'}(\tau_-))$. In particular, $\angle_{\bar{m}_2}^{\zeta}(\bar{p}_2, \bar{m}_1) = 0$ if s is sufficiently large.

Since m_2 is arbitrarily close to the parallel set if s is sufficiently large, it follows by another limiting argument that $\angle_{m_2}^{\zeta}(p_2, m_1) \leq \frac{\epsilon}{2}$ if s is sufficiently large.

Regarding the spacing, we use that $\bar{m}_1 \in V(\bar{p}_2, \text{st}_{\Theta'}(\tau_-))$ and $\bar{m}_2 \in V(\bar{p}_2, \text{st}_{\Theta'}(\tau_+))$. It follows that

$$d(\bar{m}_1, \bar{m}_2) \geq c \cdot (d(\bar{m}_1, \bar{p}_2) + d(\bar{p}_2, \bar{m}_2))$$

with a constant $c = c(\Theta') > 0$, and hence that $d(m_1, m_2) \geq l$ if s is sufficiently large. \square

Theorem 7.2 and Proposition 7.16 tell that the Morse property for quasigeodesics is equivalent to straightness (of associated spaced sequences of points). Since straightness is a local condition, this leads to a local to global result for Morse quasigeodesics, namely that the Morse property holds globally if it holds locally up to a sufficiently large scale.

Definition 7.17 (Local Morse quasigeodesic). An (L, A, Θ, D, S) -local Morse quasigeodesic in X is a map $p : I \rightarrow X$ such that for all t_0 the subpath $p|_{[t_0, t_0+S]}$ is an (L, A, Θ, D) -Morse quasigeodesic.

Note that local Morse quasigeodesics are uniformly coarse Lipschitz.

Theorem 7.18 (Local to global for Morse quasigeodesics). For L, A, Θ, Θ', D exist S, L', A', D' such that every (L, A, Θ, D, S) -local Morse quasigeodesic in X is an (L', A', Θ', D') -Morse quasigeodesic.

Proof. We choose an auxiliary Weyl convex subset Θ'' depending on Θ, Θ' such that $\Theta \subset \text{int}(\Theta'')$ and $\Theta'' \subset \text{int}(\Theta')$.

Let $p : I \rightarrow X$ be an (L, A, Θ, D, S) -local Morse quasigeodesic. We consider its coarsification on a (large) scale s and the associated midpoint sequence, i.e. we put $p_n^s = p(ns)$ and $m_n^s = \text{mid}(p_n^s, p_{n+1}^s)$. Whereas the coarsification itself does in general not become arbitrarily straight as the scale s increases, this is true for its midpoint sequence due to Proposition 7.16. We want it to be sufficiently straight and spaced so that we can apply to it the Morse Lemma from Theorem 7.2. Therefore we first fix an auxiliary constant δ , and further auxiliary constants l, ϵ as determined by Theorem 7.2 in terms of Θ', Θ'' and δ . Then Proposition 7.16 applied to the (L, A, Θ, D) -Morse quasigeodesics $p|_{[t_0, t_0+S]}$ yields that (m_n^s) is (Θ'', ϵ) -straight and l -spaced if $S \geq 3s$ and the scale s is large enough depending on $L, A, \Theta, \Theta'', D, \epsilon, l$.

Now we can apply Theorem 7.2 to (m_n^s) . It yields a nearby sequence (\bar{m}_n^s) , $d(\bar{m}_n^s, m_n^s) \leq \delta$, with the following property: For all $n_1 < n_2 < n_3$ the segments $\bar{m}_{n_1}^s \bar{m}_{n_3}^s$ are uniformly regular and the points $m_{n_2}^s$ are δ -close to the diamonds $\diamond_{\Theta'}(\bar{m}_{n_1}^s, \bar{m}_{n_3}^s)$.

Since the subpaths $p|_{[ns, (n+1)s]}$ filling in (p_n^s) are (L, A) -quasigeodesics (because $S \geq s$), and it follows that for all $t_1, t_2 \in I$ the subpaths $p|_{[t_1, t_2]}$ are D' -close to Θ' -diamonds with D' depending on L, A, s .

The conclusion of Theorem 7.2 also implies a global spacing for the sequence (m_n^s) , compare Remark 7.4, i.e. $d(m_n^s, m_{n'}^s) \geq c \cdot |n - n'|$ with a positive constant c depending on Θ', l . Hence p is a global (L', A') -quasigeodesic with L', A' depending on L, A, s, c .

Combining this information, we obtain that p is an (L', A', Θ', D') -Morse quasigeodesic for certain constants L', A' and D' depending on L, A, Θ, Θ' and D , provided that the scale S is sufficiently large in terms of the same data. \square

We discuss now the asymptotics of Morse quasigeodesics.

There is much freedom for the asymptotic behavior of arbitrary quasigeodesics in euclidean spaces, and therefore also in symmetric spaces of higher rank. However, the asymptotic behavior of Morse quasigeodesics is as restricted as for quasigeodesics in rank one symmetric spaces.

Morse quasirays do in general not converge at infinity, but they τ_{mod} -converge at infinity, compare Remark 7.11. This is a consequence of:

Lemma 7.19 (Conicality). *Every Morse quasiray $p : [0, \infty) \rightarrow X$ is uniformly Hausdorff close to a cone $V(p(0), \text{st}_\Theta(\tau))$ for a unique simplex τ of type τ_{mod} .*

Proof. The subpaths $p|_{[0, t_0]}$ are uniformly Hausdorff close to Θ -diamonds. These subconverge to a cone $V(x, \text{st}_\Theta(\tau))$ x uniformly close to $p(0)$ and τ a simplex of type τ_{mod} . This establishes the existence. Since $p(n) \xrightarrow{f} \tau$, the uniqueness of τ may be deduced from the uniqueness of τ_{mod} -limits, cf. Lemma 5.15. \square

Definition 7.20 (End of Morse quasiray). We call the unique simplex given by the previous lemma the *end* of the Morse quasiray $p : [0, \infty) \rightarrow X$ and denote it by

$$p(+\infty) \in \text{Flag}(\tau_{mod}).$$

Hausdorff close Morse quasirays have the same end, again by Lemma 5.15, and this lemma also implies the continuous dependence of the end on the Morse quasiray:

Lemma 7.21 (Continuity of end). *The assignment $p \mapsto p(+\infty)$ is a continuous map from the space of Morse quasirays $[0, +\infty) \rightarrow X$ with fixed data, equipped with the topology of pointwise convergence (equivalently, uniform convergence on compacts), to $\text{Flag}(\tau_{mod})$.*

7.4 Morse embeddings

We consider maps into X from metric spaces which are coarsely geodesic in the sense that their points can be connected by uniform quasigeodesics.

Definition 7.22 (Quasigeodesic metric space). A metric space is called (l, a) -*quasigeodesic* if pairs of points can be connected by (l, a) -quasigeodesics. It is called *quasigeodesic* if it is (l, a) -quasigeodesic for some parameters l, a .

The quasigeodesic spaces considered in this paper are discrete groups equipped with word metrics.

Definition 7.23 (Morse embedding). A *Morse embedding* from a quasigeodesic space Z into X is a map $f : Z \rightarrow X$ which sends uniform quasigeodesics in Z to uniform Morse quasigeodesics in X . We call it a Θ -*Morse embedding* if it sends uniform quasigeodesics to uniform Θ -Morse quasigeodesics.

Thus, to be a Morse embedding means that for any parameters l, a the (l, a) -quasigeodesics in Z are mapped to (L, A, Θ, D) -Morse quasigeodesics in X with the parameters L, A, Θ, D depending on l, a .

Note that Morse embeddings are quasi-isometric embeddings.

Our definition is chosen so that it depends only on the quasi-isometry class of Z whether a map $f : Z \rightarrow X$ is a (Θ) -Morse embedding, i.e. the precomposition of a (Θ) -Morse embedding

with a quasi-isometry is again (Θ) -Morse. For this to be true is why we require control on the images of quasigeodesics of arbitrarily bad quality.

However, as we observe next, in the case of maps from Gromov hyperbolic spaces control on the images of quasigeodesics of a fixed quality suffices. This is due to the Morse Lemma for quasigeodesics in Gromov hyperbolic spaces. We recall that it asserts that quasigeodesics with the same endpoints are uniformly close to each other, the closeness depending on the quasi-isometry and hyperbolicity constants.

Lemma 7.24. *Let $f : Z \rightarrow X$ be a map from a Gromov hyperbolic space Z into X . If Z is (l, a) -quasigeodesic and if f sends (l, a) -quasigeodesics to uniform Θ -Morse quasigeodesics, then f is a Θ -Morse embedding.*

Proof. This is a consequence of the definition of Morse quasigeodesics, see Definition 7.14 and the Morse Lemma applied to Z . \square

We now deduce from our local to global result for Morse quasigeodesics, see Theorem 7.18, a local to global result for Morse embeddings.

Since we need to fix one scale of localness, we can expect a local to global control for the f -images of quasigeodesics in Z only if they have a certain fixed quality. This is why we need to restrict to maps from Gromov hyperbolic spaces.

Definition 7.25 (Local Morse embedding). We call a map $f : Z \rightarrow X$ from a quasigeodesic space Z into X an $(l, a, L, A, \Theta, D, S)$ -local Morse embedding if Z is (l, a) -quasigeodesic and if for any (l, a) -quasigeodesic $q : I \rightarrow Z$ defined on an interval I of length $\leq S$ the image path $f \circ q$ is an (L, A, Θ, D) -Morse quasigeodesic in X .

Theorem 7.26 (Local-to-global for Morse embeddings of Gromov hyperbolic spaces). *For $l, a, L, A, \Theta, \Theta', D$ exists a scale S such that every $(l, a, L, A, \Theta, D, S)$ -local Morse embedding from a quasigeodesic Gromov hyperbolic space into X is a Θ' -Morse embedding.*

Proof. Let $f : Z \rightarrow X$ denote the local Morse embedding. It sends every (l, a) -quasigeodesic $q : I \rightarrow Z$ to a (L, A, Θ, D, S) -local Morse quasigeodesic $p = f \circ q$ in X . By Theorem 7.18, p is (L', A', Θ', D') -Morse if S is sufficiently large, where L', A', D' depend on the given data. Lemma 7.24 implies that f is a Θ' -Morse embedding. \square

We now discuss the asymptotics of Morse embeddings.

Morse embeddings $f : Z \rightarrow X$ map sufficiently spaced pairs of points to uniformly τ_{mod} -regular pairs of points. Therefore, their images accumulate in the τ_{mod} -regular part of $\partial_\infty X$ and there is a well-defined *flag limit set*

$$\Lambda_{\tau_{mod}}(f) \subset \text{Flag}(\tau_{mod}). \quad (7.27)$$

For Morse embeddings $f : Z \rightarrow X$ of Gromov hyperbolic spaces Z we obtain, by applying our discussion of the asymptotics of Morse quasirays, a well-defined continuous boundary map at infinity

$$\partial_\infty f : \partial_\infty Z \rightarrow \text{Flag}(\tau_{mod}) \quad (7.28)$$

which sends the ideal endpoint $q(+\infty)$ of a quasiray $q : [0, +\infty) \rightarrow Z$ to the end $(f \circ q)(+\infty)$ of the image Morse quasiray. The continuity of $\partial_\infty f$ follows from Lemma 7.21.

Proposition 7.29 (Asymptotic properties of Morse embeddings). *Let $f : Z \rightarrow X$ be a Morse embedding from a proper, quasigeodesic Gromov hyperbolic space Z .*

(i) *f is τ_{mod} -conical in the sense that f sends each quasigeodesic ray q in Z to a quasigeodesic ray p in X so that the sequence $(p(n))$ converges conically to the simplex $\partial_\infty f(q(+\infty))$.*

(ii) *$\partial_\infty f$ is antipodal, i.e. it maps distinct ideal points to antipodal simplices.*

(iii) *f has nice asymptotics, i.e. $\partial_\infty f$ is a homeomorphism onto $\Lambda_{\tau_{mod}}(f)$.*

Proof. (i) This is a consequence of Lemma 7.19 applied to the f -images of quasirays in Z .

(ii) By hyperbolicity and the quasigeodesic properties of Z , any two distinct points in $\partial_\infty Z$ can be connected by a quasigeodesic $q : \mathbb{R} \rightarrow Z$. Then $f \circ q$ is a Morse quasigeodesic. Since Morse quasigeodesics are Hausdorff close to biinfinite straight spaced sequences (Proposition 7.16), and such sequences satisfy a Morse Lemma (Theorem 7.2) and therefore τ_{mod} -converge to a pair of opposite simplices, the assertion follows.

(iii) Our argument follows the end of the proof of Theorem 6.48. By construction of the boundary map $\partial_\infty f$, its image is contained in the limit set $\Lambda_{\tau_{mod}}(f)$. It is injective by antipodality. To prove surjectivity, let $\tau \in \Lambda_{\tau_{mod}}(f)$, and let $z_n \rightarrow \infty$ be a sequence in Z so that $f(z_n) \rightarrow \tau$ in the sense of τ_{mod} -convergence. Since Z is quasigeodesic, there exists a sequence of uniform quasigeodesic segments $q_n : [0, l_n] \rightarrow Z$ connecting a base point to z_n . After passing to a subsequence, the q_n converge to a quasiray $q_\infty : [0, +\infty) \rightarrow Z$ because Z is proper. We need to verify that $(f \circ q_\infty)(+\infty) = \tau$.

Let $t_n \rightarrow +\infty$ be a sequence of times $t_n \leq l_n$. Then the Morse property of $f \circ q_n$ and Lemma 5.15 imply that $(f \circ q_n)(t_n) \rightarrow \tau$. We can choose the t_n so that $q_n(t_n)$ is uniformly close to q_∞ . The Morse property of $f \circ q_\infty$ implies that $(f \circ q_n)(t_n)$ is uniformly close to a Θ -cone $V(x, \text{st}_\Theta((f \circ q_\infty)(+\infty)))$. Applying Lemma 5.15 again, we conclude that $\tau = (f \circ q_\infty)(+\infty) = \partial_\infty f(q_\infty(+\infty))$, i.e. τ is in the image of $\partial_\infty f$. \square

7.5 Morse actions

We consider isometric actions $\Gamma \curvearrowright X$ of finitely generated groups.

Definition 7.30 (Morse action). We call an action $\Gamma \curvearrowright X$ Θ -Morse if one (any) orbit map $\Gamma \rightarrow \Gamma x \subset X$ is a Θ -Morse embedding with respect to a(ny) word metric on Γ . We call an action $\Gamma \curvearrowright X$ τ_{mod} -Morse if it is Θ -Morse for some τ_{mod} -Weyl convex compact subset $\Theta \subset \text{ost}(\tau_{mod})$.

Remark 7.31 (Morse actions are weakly regular and undistorted). (i) It follows immediately from the definition of Morse quasigeodesics that Θ -Morse actions are τ_{mod} -regular for the simplex type τ_{mod} determined by Θ .

(ii) Morse actions are *undistorted* in the sense that the orbit maps are quasi-isometric embeddings. In particular, they are properly discontinuous.

We denote by $\text{Hom}_M(\Gamma, G) \subset \text{Hom}(\Gamma, G)$ the subset of Morse actions $\Gamma \curvearrowright X$.

By analogy with *local Morse quasigeodesics*, we define *local Morse group actions* $\rho : \Gamma \curvearrowright X$ of a hyperbolic group (with fixed generating set):

Definition 7.32. An action ρ is called (L, A, Θ, D, S) -*locally Morse*, or (l, a, L, A, Θ, D) -*locally Morse on the scale S* , if the orbit map $\Gamma \rightarrow \Gamma \cdot x \subset X$ is an $(l, a, L, A, \Theta, D, S)$ -local Morse embedding.

According to our local to global result for Morse embeddings, see Theorem 7.26, an action of a word hyperbolic group is Morse if and only if it is local Morse on a sufficiently large scale. Since this is a finite condition, it follows that the Morse property is stable under perturbation of the action:

Theorem 7.33 (Morse is open for word hyperbolic groups). *For any word hyperbolic group Γ the subset $\text{Hom}_M(\Gamma, G)$ is open in $\text{Hom}(\Gamma, G)$.*

Proof. Let $\rho : \Gamma \curvearrowright X$ be a Morse action. We fix a word metric on Γ and a base point $x \in X$. Then there exist data (L, A, Θ, D) such that the orbit map $\Gamma \rightarrow \Gamma x \subset X$ sends is an (L, A) -quasi-isometric embedding, which sends (discrete) geodesics to (L, A, Θ, D) -Morse quasigeodesics.

We relax the Morse parameters slightly, i.e. we consider (L, A, Θ, D) -Morse quasigeodesics as $(L, A + 1, \Theta, D + 1)$ -Morse quasigeodesics satisfying strict inequalities. For every scale S , the orbit map is, in particular, an $(L, A + 1, \Theta, D + 1, S)$ -local Morse embedding. Due to Γ -equivariance, this is a finite condition in the sense that it is equivalent to a condition involving only finitely many orbit points. Since we relaxed the Morse parameters, the same condition is satisfied by all actions sufficiently close to ρ .

Theorem 7.26 provides a scale S such that $(L, A + 1, \Theta, D + 1, S)$ -local Morse embeddings are global Morse. (More precisely, they are uniform Θ' -Morse embeddings.) It follows that actions sufficiently close to ρ are (Θ') -Morse. \square

Corollary 7.34. *For every hyperbolic group Γ the space of faithful Morse representations*

$$\text{Hom}_{f,M}(\Gamma, G)$$

is open in $\text{Hom}_M(\Gamma, G)$.

Proof. Every hyperbolic group Γ has the unique maximal finite normal subgroup $F \triangleleft \Gamma$ (if Γ is nonelementary then F is the kernel of the action of Γ on $\partial_\infty \Gamma$). Since Morse actions are properly discontinuous, kernel of every Morse representation $\Gamma \rightarrow G$ is contained in F . Since $\text{Hom}(F, G)/G$ is finite, it follows that the set of faithful Morse representations is open in $\text{Hom}_M(\Gamma, G)$. \square

We now turn to asymptotic properties of Morse actions. We apply our earlier discussion of the asymptotics of Morse embeddings.

For a Morse action $\rho : \Gamma \curvearrowright X$, the limit sets (7.27) of the orbit maps coincide with the limit set $\Lambda_{\tau_{mod}}(\rho(\Gamma))$ of the subgroup $\rho(\Gamma) \subset G$. If Γ is word hyperbolic group, then the boundary map (7.28) induced by the orbit maps yield a well-defined Γ -equivariant homeomorphism at infinity

$$\partial_\infty \rho : \partial_\infty \Gamma \xrightarrow{\cong} \Lambda_{\tau_{mod}}(\Gamma) \subset \text{Flag}(\tau_{mod})$$

which does not depend on the Γ -orbit, cf. Proposition 7.29. The same proposition implies together with the fact that Morse embeddings are uniformly regular:

Theorem 7.35 (Asymptotic characterization of Morse actions). *An action of a word hyperbolic group is τ_{mod} -Morse if and only if it is τ_{mod} -asymptotically embedded.*

Proof. One direction follows from the discussion above, the converse from Theorem 6.33. \square

Our result on the openness of the Morse condition for actions of word hyperbolic groups, cf. Theorem 7.33, can be strengthened in the sense that the asymptotics of Morse actions vary continuously:

Theorem 7.36 (Morse actions are structurally stable). *The boundary map at infinity of a Morse action depends continuously on the action.*

Proof. Nearby actions are uniformly Morse, see the proof of Theorem 7.33. The assertion therefore follows from the fact that the ends of Morse quasirays vary continuously, cf. Lemma 7.21. \square

Remark 7.37. (i) Note that since the boundary maps at infinity are embeddings, the Γ -actions on the τ_{mod} -limit sets are topologically conjugate to each other and, for nearby actions, by a homeomorphism close to the identity.

(ii) In rank one, our argument yields a different proof for Sullivan's Structural Stability Theorem [Su] for convex cocompact group actions.

7.6 Schottky actions

In this section we apply our local-to-global result for straight sequences (Theorem 7.2) to construct Morse actions of free groups, generalizing and sharpening¹ Tits's ping-pong construction.

We consider two oriented τ_{mod} -regular geodesic lines a, b in X . Let $\tau_{\pm a}, \tau_{\pm b} \in \text{Flag}(\tau_{mod})$ denote the simplices which they are τ -asymptotic to, and let $\theta_{\pm a}, \theta_{\pm b} \in \sigma_{mod}$ denote the types of their forward/backward ideal endpoints in $\partial_\infty X$. (Note that $\theta_{-a} = \iota(\theta_a)$ and $\theta_{-b} = \iota(\theta_b)$.) Let Θ be a compact convex subset of $\text{ost}(\tau_{mod}) \subset \sigma_{mod}$, which is invariant under ι .

Definition 7.38 (Generic pair of geodesics). We call the pair of geodesics (a, b) *generic* if the four simplices $\tau_{\pm a}, \tau_{\pm b}$ are pairwise opposite.

¹In the sense that we obtain free subgroups which are not only embedded, but also asymptotically embedded in G .

Let $\alpha, \beta \in G$ be axial isometries with axes a and b respectively and translating in the positive direction along these geodesics. Then $\tau_{\pm a}$ and $\tau_{\pm b}$ are the attractive/repulsive fixed points of α and β on $\text{Flag}(\tau_{\text{mod}})$.

For every pair of numbers $m, n \in \mathbb{N}$ we consider the representation of the free group in two generators

$$\rho_{m,n} : F_2 = \langle A, B \rangle \rightarrow G$$

sending the generator A to α^m and B to β^n . We regard it as an isometric action $\rho_{m,n} : F_2 \curvearrowright X$.

Definition 7.39 (Schottky subgroup). A τ_{mod} -Schottky subgroup of G is a free τ_{mod} -asymptotically embedded subgroup of G .

If G has rank one, this definition amounts to the requirement that Γ is convex cocompact and free. Equivalently, this is a discrete finitely generated subgroup of G which contains no nontrivial elliptic and parabolic elements and has totally disconnected limit set (see [Ka]). We note that this definition essentially agrees with the standard definition of Schottky groups in rank 1 Lie groups, provided one allows fundamental domains at infinity for such groups to be bounded by pairwise disjoint compact submanifolds which need not be topological spheres, see [Ka] for the detailed discussion.

Theorem 7.40 (Morse Schottky actions). *If the pair of geodesics (a, b) is generic and if $\theta_{\pm a}, \theta_{\pm b} \in \text{int}(\Theta)$, then the action $\rho_{m,n}$ is Θ -Morse for sufficiently large m, n . Thus, such $\rho_{m,n}$ is injective and its image is a τ_{mod} -Schottky subgroup of G .*

Remark 7.41. In particular, these actions are faithful and undistorted, compare Remark 7.31.

Proof. Let $S = \{A^{\pm 1}, B^{\pm 1}\}$ be the standard generating set. We consider the sequences (γ_k) in F_2 with the property that $\gamma_k^{-1}\gamma_{k+1} \in S$ and $\gamma_{k+1} \neq \gamma_{k-1}$ for all k . They correspond to the geodesic segments in the Cayley tree of F_2 associated to S which connect vertices.

Let $x \in X$ be a base point. In view of Lemma 7.24 we must show that the corresponding sequences $(\gamma_k x)$ in the orbit $F_2 \cdot x$ are uniformly Θ -Morse. (Meaning e.g. that the maps $\mathbb{R} \rightarrow X$ sending the intervals $[k, k+1)$ to the points $\gamma_k x$ are uniform Θ -Morse quasigeodesics.) As in the proof of Theorem 7.18 we will obtain this by applying our local to global result for straight spaced sequences (Theorem 7.2) to the associated midpoint sequences. Note that the sequences $(\gamma_k x)$ themselves cannot be expected to be straight.

Taking into account the Γ -action, the uniform straightness of all midpoint sequences depends on the geometry of a finite configuration in the orbit. It is a consequence of the following fact. Consider the midpoints $y_{\pm m}$ of the segments $x\alpha^{\pm m}(x)$ and $z_{\pm n}$ of the segments $x\beta^{\pm n}(x)$.

Lemma 7.42. *For sufficiently large m, n the quadruple $\{y_{\pm m}, z_{\pm n}\}$ is arbitrarily separated and Θ -regular. Moreover, for any of the four points, the segments connecting it to the other three points have arbitrarily small ζ -angles with the segment connecting it to x .*

Proof. The four points are arbitrarily separated from each other and from x because the axes a and b diverge from each other due to our genericity assumption.

By symmetry, it suffices to verify the rest of the assertion for the point y_m , i.e. we show that the segments $y_m y_{-m}$ and $y_m z_n$ are Θ -regular for large m, n and that $\lim_{m \rightarrow \infty} \angle_{y_m}^\zeta(x, y_{-m}) = 0$ and $\lim_{n, m \rightarrow \infty} \angle_{y_m}^\zeta(x, z_n) = 0$.

The orbit points $\alpha^{\pm m}x$ and the midpoints $y_{\pm m}$ are contained in a tubular neighborhood of the axis a . Therefore, the segments $y_m x$ and $y_m y_{-m}$ are Θ -regular for large m and $\angle_{y_m}(x, y_{-m}) \rightarrow 0$. This implies that also $\angle_{y_m}^\zeta(x, y_{-m}) \rightarrow 0$.

To verify the assertion for (y_m, z_n) we use that, due to genericity, the simplices τ_a and τ_b are opposite and we consider the parallel set $P = P(\tau_a, \tau_b)$. Since the geodesics a and b are forward asymptotic to P , it follows that the points x, y_m, z_n have uniformly bounded distance from P . We denote their projections to P by $\bar{x}, \bar{y}_m, \bar{z}_n$.

Let $\Theta'' \subset \text{int}(\Theta)$ be an auxiliary Weyl convex subset such that $\theta_{\pm a}, \theta_{\pm b} \in \text{int}(\Theta'')$. We have that $\bar{y}_m \in V(\bar{x}, \text{st}_{\Theta''}(\tau_a))$ for large m because the points y_m lie in a tubular neighborhood of the ray with initial point \bar{x} and asymptotic to a . Similarly, $\bar{z}_n \in V(\bar{x}, \text{st}_{\Theta''}(\tau_b))$ for large n . It follows that $\bar{x} \in V(\bar{y}_m, \text{st}_{\Theta''}(\tau_b))$ and, using the convexity of Θ -cones (Proposition 2.18), that $\bar{z}_n \in V(\bar{y}_m, \text{st}_{\Theta''}(\tau_b))$.

The cone $V(y_m, \text{st}_{\Theta''}(\tau_b))$ is uniformly Hausdorff close to the cone $V(\bar{y}_m, \text{st}_{\Theta''}(\tau_b))$ because the Hausdorff distance of the cones is bounded by the distance $d(y_m, \bar{y}_m)$ of their tips. Hence there exist points $x', z'_n \in V(y_m, \text{st}_{\Theta''}(\tau_b))$ uniformly close to x, z_n . Since $d(y_m, x'), d(y_m, z'_n) \rightarrow \infty$ as $m, n \rightarrow \infty$, it follows that the segments $y_m x$ and $y_m z_n$ are Θ -regular for large m, n . Furthermore, since $\angle_{y_m}^\zeta(x', z'_n) = 0$ and $\angle_{y_m}(x, x') \rightarrow 0$ as well as $\angle_{y_m}(z_n, z'_n) \rightarrow 0$, it follows that $\angle_{y_m}^\zeta(x, z_n) \rightarrow 0$. \square

Proof of Theorem concluded. The lemma implies that for any given l, ϵ the midpoint triples of the four point sequences $(\gamma_k x)$ are (Θ, ϵ) -straight and l -spaced if m, n are sufficiently large, compare the quadruple condition (Definition 7.15). This means that the midpoint sequences of all sequences $(\gamma_k x)$ are (Θ, ϵ) -straight and l -spaced for large m, n . Theorem 7.2 then implies that the sequences $(\gamma_k x)$ are uniformly Θ -Morse. \square

Remark 7.43. Generalizing the above argument to free groups with finitely many generators, one can construct Morse Schottky subgroups for which the set $\theta(\Lambda) \subset \sigma_{\text{mod}}$ of types of limit points is arbitrarily Hausdorff close to a given ι -invariant Weyl convex subset Θ . This provides an alternative approach to the second main theorem in [Ben] using geometric arguments.

7.7 Algorithmic recognition of Morse actions

In this section, we describe an algorithm which has an isometric action $\rho : \Gamma \curvearrowright X$ and a point $x \in X$ as its input and terminates if and only if the action ρ is Morse (otherwise, the algorithm runs forever).

We begin by describing briefly a *Jørgensen's algorithm* accomplishing a similar task, namely, detecting geometrically finite actions on $X = \mathbb{H}^3$. Suppose that we are given a finite (symmetric) set of generators $g_1 = 1, \dots, g_m$ of a subgroup $\Gamma \subset PO(3, 1)$ and a base-point $x \in X = \mathbb{H}^n$. The idea of Jørgensen's algorithm is to construct a finite sided Dirichlet fundamental domain

D for Γ (with the center at x): Every geometrically finite subgroup of $PO(3,1)$ admits such a domain. (The latter is false for geometrically finite subgroups of $PO(n,1)$, $n \geq 4$, but is, nevertheless true for convex cocompact subgroups.) Given a finite sided convex fundamental domain, one concludes that Γ is geometrically finite. Here is how the algorithm works: For each k define the subset $S_k \subset \Gamma$ represented by words of length $\leq k$ in the letters g_1, \dots, g_m . For each $g \in S_k$ consider the half-space $Bis(x, g(x)) \subset X$ bounded by the bisector of the segment $xg(x)$ and containing the point x . Then compute the intersection

$$D_k = \bigcap_{g \in S_k} Bis(x, g(x)).$$

Check if D_k satisfies the conditions of the *Poincaré's Fundamental Domain theorem*. If it does, then $D = D_k$ is a finite sided fundamental domain of Γ . If not, increase k by 1 and repeat the process. Clearly, this process terminates if and only if Γ is geometrically finite.

One can enhance the algorithm in order to detect if a geometrically finite group is convex cocompact. Namely, after a Dirichlet domain D is constructed, one checks for the following:

1. If the ideal boundary of a Dirichlet domain D has isolated ideal points (they would correspond to rank two cusps which are not allowed in convex cocompact groups).
2. If the ideal boundary of D contains tangent circular arcs with points of tangency fixed by parabolic elements (coming from the “ideal vertex cycles”). Such points correspond to rank 1 cusps, which again are not allowed in convex cocompact groups.

Checking 1 and 2 is a finite process; after its completion, one concludes that Γ is convex cocompact.

We now consider group actions on general symmetric spaces. Let Γ be a hyperbolic group with a fixed finite (symmetric) generating set; we equip the group Γ with the word metric determined by this generating set.

For each n , let \mathcal{L}_n denote the set of maps $q : [0, 3n] \cap \mathbb{Z} \rightarrow \Gamma$ which are restrictions of geodesics $\tilde{q} : \mathbb{Z} \rightarrow \Gamma$, so that $q(0) = 1 \in \Gamma$. In view of the geodesic automatic structure on Γ (see e.g. [Ep, Theorem 3.4.5]), the set \mathcal{L}_n can be described via a finite state automaton.

Suppose that $\rho : \Gamma \curvearrowright X$ is an isometric action on a symmetric space X ; we fix a base-point $x \in X$ and the corresponding orbit map $f : \Gamma \rightarrow \Gamma x \subset X$. We also fix an ι -invariant face τ_{mod} of the model spherical simplex σ_{mod} of X . The algorithm that we are about to describe will detect that the action ρ is τ_{mod} -Morse.

Remark 7.44. If the face τ_{mod} is not fixed in advance, we would run algorithms for each face τ_{mod} in parallel.

For the algorithm we will be using a special (countable) increasing family of Weyl-convex compact subsets $\Theta = \Theta_i \subset \text{ost}(\tau_{mod}) \subset \sigma_{mod}$ which exhausts $\text{ost}(\tau_{mod})$; in particular, every compact ι -invariant convex subset of $\text{ost}(\tau_{mod}) \subset \sigma_{mod}$ is contained in some Θ_i :

$$\Theta_i := \left\{ v \in \sigma : \min_{\alpha \in \Phi_{\tau_{mod}}} \alpha(v) \geq \frac{1}{i} \right\}, \quad (7.45)$$

where $\Phi_{\tau_{mod}}$ is the subset of the set of simple roots Φ (with respect to σ_{mod}) which vanish on the face τ_{mod} . Clearly, the sets Θ_i satisfy the required properties. Furthermore, we consider only those L and D which are natural numbers.

Next, consider the sequence

$$(L_i, \Theta_i, D_i) = (i, \Theta_i, D_i), i \in \mathbb{N}.$$

In order to detect τ_{mod} -Morse actions we will use the local characterization of Morse quasi-geodesics given by Theorem 7.2 and Proposition 7.16. Due to the discrete nature of quasi-geodesics that we will be considering, it suffices to assume that the additive quasi-isometry constant A is zero.

Consider the functions

$$l(\Theta, \Theta', \delta), \epsilon(\Theta, \Theta', \delta)$$

as in Theorem 7.2. Using these functions, for the sets $\Theta = \Theta_i, \Theta' = \Theta_{i+1}$ and the constant $\delta = 1$ we define the numbers

$$l_i = l(\Theta, \Theta', \delta), \epsilon_i = \epsilon(\Theta, \Theta', \delta).$$

Next, for the numbers $L = L_i, D = D_i$ and the sets $\Theta = \Theta_i, \Theta' = \Theta_{i+1}$, consider the numbers

$$s_i = s(L_i, 0, \Theta_i, \Theta_{i+1}, D_i, \epsilon_{i+1}, l_{i+1})$$

as in Proposition 7.16. According to this proposition, every $(L_i, 0, \Theta_i, D_i)$ -Morse quasigeodesic satisfies the $(\Theta_{i+1}, \epsilon_{i+1}, l_{i+1}, s)$ -quadruple condition for all $s \geq s_i$. We note that, a priori, the sequence s_i need not be increasing. We set $S_1 = s_1$ and define a monotonic sequence S_i recursively by

$$S_{i+1} = \max(S_i, s_{i+1}).$$

Then every $(L_i, 0, \Theta_i, D_i)$ -Morse quasigeodesic also satisfies the $(\Theta_{i+1}, \epsilon_{i+1}, l_{i+1}, S_{i+1})$ -quadruple condition.

We are now ready to describe the algorithm. For each $i \in \mathbb{N}$ we compute the numbers l_i, ϵ_i and, then, S_i , as above. We then consider finite discrete paths in Γ , $q \in \mathcal{L}_{S_i}$, and the corresponding discrete paths in X , $p(t) = q(t)x$, $t \in [0, 3S_i] \cap \mathbb{Z}$. The number of paths q (and, hence, p) for each i is finite, bounded by the growth function of the group Γ .

For each discrete path p we check the $(\Theta_i, \epsilon_i, l_i, S_i)$ -quadruple condition. If for some $i = i_*$, all paths p satisfy this condition, the algorithm terminates: It follows from Theorem 7.2 that the map f sends all normalized discrete biinfinite geodesics in Γ to Morse quasigeodesics in X . Hence, the action $\Gamma \curvearrowright X$ is Morse in this case. Conversely, suppose that the action of Γ is $(L, 0, \Theta, D)$ -Morse. Then f sends all isomeric embeddings $\tilde{q} : \mathbb{Z} \rightarrow \Gamma$ to $(L, 0, \Theta, D)$ -Morse quasigeodesics \tilde{p} in X . In view of the properties of the sequence

$$(L_i, \Theta_i, D_i),$$

it follows that for some i ,

$$(L, \Theta, D) \leq (L_i, \Theta_i, D_i),$$

i.e., $L \leq L_i, \Theta \subset \Theta_i, D \leq D_i$; hence, all the biinfinite discrete paths \tilde{p} are $(L_i, 0, \Theta_i, D_i)$ -Morse quasigeodesic. By the definition of the numbers l_i, ϵ_i, S_i , it then follows that all the discrete paths $p = f \circ q, q \in \mathcal{L}_{S_i}$ satisfy the $(\Theta_{i+1}, \epsilon_{i+1}, l_{i+1}, S_{i+1})$ -quadruple condition. Thus, the algorithm will terminate at the step $i + 1$ in this case.

Therefore, the algorithm terminates if and only if the action is Morse (for some parameters). If the action is not Morse, the algorithm will run forever. \square
